The architecture is illustrated in Figure 1. For clarity, the connections are shown only for a single component, but all components function in parallel in the same way. The diamonds on the diagram represent Q-gates, trainable logic components which we will now describe.

4.2 Q-gates – logic for absent components

In high-dimensional domains, items usually do not exercise all skill components simultaneously. For instance, in both assessment and instruction, questions are usually designed to focus on a subset of skills. Rather than model the subset of skills explicitly, we iterate across the whole domain K and let a logic layer selectively deactivate components:

$$Pr(X_{si} = 1 \mid \theta_s, \beta_i) = \prod_{k \in K} G_q(q_{sk}, q_{ik}, \sigma(\theta_{sk}, \beta_{ik})) \quad (5)$$

G_q is a *Q-gate*, a ternary logic gate related to logical implication, with the following truth table for each component per student, q_{sk} , and per item, q_{ik} :

q_{ik}	q_{sk}	G_q
1	1	$\sigma(\theta_{sk}, \beta_{ik})$
1	0	0
0	1	1
0	0	1

Q-gates are implemented as part of the neural network, and modify the component-level sigmoid outputs:

$$G_q(q_{sk}, q_{ik}, \sigma(\theta_{sk}, \beta_{ik})) = \sigma(\theta_{sk}, \beta_{ik}) q_{ik} q_{sk} + (1 - q_{ik}) \quad (6)$$

The correct values for q_{ik} and q_{sk} are learned during training. These *q-values* can either be stored in their own set of weights, or represented by special values in θ and β . We use the latter technique with *weight clipping*, explained next.

4.3 Weight clipping

We employ *weight clipping* for two reasons: to ensure component positivity (so that vector magnitude must grow with skill), and to implement Q-gates. To ensure components take only positive values, weights are clipped to $[1, W]$, with large W to allow for changes in value during training. The range $[0, 1)$ is reserved to switch the component’s Q-gate.

4.4 Training

The network was trained with a categorical cross-entropy loss function and the Adam optimiser [3]. Generally, training is fast, and a learning rate $\alpha \in [0.01, 0.1]$ is stable. Weight initialisation is significant for convergence speed and fit: a uniform random initialisation over $[\theta_{min}, \theta_{max}]$ for students and $[\beta_{min}, \beta_{max}]$ for items was found to work well. From all instances in the training set, 10% were randomly chosen for validation and to trigger early-stopping on $loss_{val}$ with *patience* = 10 (i.e. we wait for a better value for ten more epochs before quitting, keeping our best weights). This work was implemented in Python 3.6 using Keras with a TensorFlow back-end, and scikit-learn.

5. EVALUATION

In this section we describe how the embeddings were evaluated *vis-à-vis* our desired characteristics.

5.1 Prediction agreement

We attempt to recreate the original datasets by using our embeddings $\hat{\theta}$ and $\hat{\beta}$ to seed our statistical MLTM model. We then score correlation and agreement between the outputs of the original process (seeded with targets θ^* and β^*) and the embedding-seeded process.

Since our dataset is synthetic, we can directly access the probabilities that determine the outcomes, and thus can measure the Pearson’s correlation between these and the predicted probabilities from the embeddings. This is:

$$\rho_{X,Y} = \frac{cov(P^*, \hat{P})}{sd(P^*), sd(\hat{P})} \quad (7)$$

where P^* and \hat{P} are the true and predicted probabilities of a pass, $cov(\cdot, \cdot)$ is covariance and $sd(\cdot)$ is standard deviation.

Because the generator process is stochastic, there will always be some element of chance in the observed outcomes. *Cohen’s Kappa* gives a measure of the agreement beyond chance. For N datapoints, where n_{agreed} is the observed agreement between both runs, and $n_{(k;seed)}$ is the number classed as category k by the model seeded with *seed*:

$$\kappa = \frac{p_o - p_e}{1 - p_e} \text{ where } \begin{cases} p_o = n_{agreed}/N \\ p_e = \frac{1}{N^2} \sum_{k \in \{T, F\}} n_{(k; \theta^* \beta^*)} n_{(k; \hat{\theta} \hat{\beta})} \end{cases} \quad (8)$$

5.2 Co-proximity & Magnitude

To assess our co-proximity requirement, we measure Euclidean distance from the aligned embedding $\hat{\theta}$ (or $\hat{\beta}$) to its target, θ^* (or β^*). We compare this to the mean distance from other vectors in the space, and test for significance to show that co-proximity to target is not merely by chance.

Figure 2: t-SNE visualisation of embeddings in a 10-dimensional space, all active, with 1000 students and 100 items (orange=embedding, blue=target).

To assess magnitude growth with skill, we use Pearson correlation (equation 7) at the component level between the elements of $\hat{\theta}$ (or $\hat{\beta}$) and of target θ^* (or β^*). A strong correlation shows that these values grow together as desired.

5.3 Aligning the components

Embeddings are identifiable only up to the ordering of the components due to conjunctive commutivity: columns in the Θ -Table will be aligned with the B-Table, since they were trained together, but they may be permuted differently to the columns in the original target vectors. To visualise the data, or calculate deviations from the true parameters, we must first align the predicted components. A hill-climbing algorithm can find the order needed to minimise the per-column squared error between the predicted and true values. While not guaranteed to find the global optimum, it is nonetheless reliable. Once the components are aligned, the embeddings can be plotted (after dimensionality reduction such as PCA or t-SNE for $|K| > 2$). The mean absolute parameter errors are given as θ_{MAE} and β_{MAE} in Table 1(b).

Figure 3 shows the mined values for a 2 KC domain, with 1-2 active components: Q-gates allow components to be switched on/off. Dotted lines show the thresholds below which the Q-gate treats a component as inactive. Figure 4 shows the mined values for a 10 KC domain, with 1-3 active components. Here the clustering of target points (blue) are more pronounced than in the all-active data (Figure 2). The embeddings (orange) cluster close to their targets due to the Q-gate mechanism.

Figure 3: Direct plot of Q-gated embeddings in a 2-dimensional space, 1000 students and 100 mixed items (50×2 -components, 50×1 -component). Dotted lines show the Q-gate activation regions.

6. RESULTS & DISCUSSION

Table 1 gives summary statistics for all-active (upper section) and Q-gated (lower section) datasets.

Table 1(a) gives raw accuracy and Cohen's κ measure agreement between true and predicted outcomes, and Pearson's ρ measures correlation between the underlying probabilities. The reproduction (*repro*) scores for *Acc* and κ show how well the original model can reproduce its own data – this indicates the level of stochastic noise in the target dataset.

Reproduction accuracy drops from 0.844 to 0.651 as domain size increases, but this is more pronounced (0.684 to 0.310) for κ , implying that much of the accuracy score is down to chance, and κ is a more useful measure. At low to moderate dimensions (1a to 10a), mined κ values approach the model's own agreement, but for the high dimension (100a) they do not even achieve half of this limit, although still better than chance ($\kappa = 0$). For Q-gated data (2q2, 10q3, 10q5, 100q5) the embeddings produce higher accuracy and κ throughout than their non-Q-gated counterparts.

Pearson's correlation on the underlying probabilities (unaffected by stochastic noise) is very good (>0.9) for all lower $|K|$ data (with or without Q-gates), but for (100a) this drops to 0.442 – the Q-gated version (100q5) scores 0.754, an improvement of over 70%.

6.1 Co-proximity & Magnitude

Table 1(c) gives mean Euclidean distances of embedding to target, alongside the mean distance to other points in the dataset. Mean and standard deviations are given along with Welch's t-test results. In all cases the mined vectors have significantly ($p < 0.01$) smaller mean distances to target than to other vectors in the space, indicating co-proximity between

Table 1: (a) Accuracy, Cohen’s κ agreement, Pearson’s correlation (ρ). The *repro* scores show how well the original dataset generator agrees with itself between runs, giving an upper limit to the score. (b) Parameter level error scores for students and items. (c) Mean Euclidean distance to target (D_{target}) and to other vectors (D_{others}), with t-test scores.

Model		(a) Model fit			(b) Param. fit.		(c) Co-proximity in vector space		
Name	Dims	Acc (repro)	κ (repro)	ρ^*	θ_{MAE}	β_{MAE}	D_{target}	D_{others}	t^{**}
1a	1	0.844 (0.844)	0.680 (0.684)	0.994	0.29	0.11	0.11 (0.09)	3.66 (0.65)	-36.9
2a	2	0.776 (0.777)	0.550 (0.556)	0.986	0.55	0.46	0.79 (0.38)	3.74 (0.80)	-33.1

10q5	10 (1-5)	0.822 (0.832)	0.503 (0.522)	0.942	1.33	0.19	1.12 (0.84)	10.53 (1.48)	-54.9
100q5	100 (1-5)	0.732 (0.821)	0.509 (0.555)	0.754	3.09	0.27	1.13 (0.84)	10.53 (1.48)	-54.0

*($p < 0.01$) ** (Welch’s t-test, $df=98$, $p < 0.01$)

Figure 4: t-SNE visualisation showing 100 items, calibrated from 1000 students. Here, only 1-3 dimensions (from 10) are active for any item. The other dimensions are masked using Q-gates.

mined and true vectors as desired. Again Q-gates have a notable effect: for instance, the quotient (D_{others}/D_{target}) increases from 1.11 for 100a to 9.30 for 100q5.

Component-level correlations for true and mined parameter values (not tabled) are strongly correlated ($\rho \geq 0.90, p = 0.01$) for low to moderate $|K| \in [1, 10]$ showing our second desired characteristic of magnitude growth with skill. As with other results, a weaker positive correlation ($\rho = 0.21, p = 0.01$) was measured for $|K| = 100$.

6.2 Skill masking

Our embeddings achieve a high correlation with target outcome probabilities for all but $|K| = 100$. Similar patterns can be seen with other scores. Overall, larger error in the

vector space (100a in Table 1(b)) seems to contribute to markedly reduced model fit (100a in Table 1(a)).

There are at least two factors at play here: firstly, for large $|K|$, the ‘curse of dimensionality’ makes distance metrics less meaningful, and it becomes difficult to determine distance (or similarity) between vectors. The second factor is informational: if an item has 100 active components, a student must achieve a pass-rate of 99.3% *on each component* to get 50% pass-rate on the item. Very easy components carry little information: our expectation that a student would pass them is almost always met. This manifests as a shallow gradient on the sigmoid in this region ($x = 4.95$), making parameter values very sensitive to stochastic noise in training data. Furthermore, dichotomous results tell us nothing about which component caused a failed attempt. These factors make for a difficult machine-learning task.

Fortunately, the Q-gated datasets show a different pattern. They behave more like low-dimensionality data: for instance, 100 (1-5 active) dimensions – *versus* 100 (all active) – shows both better probability correlation ($0.75 > 0.44$), and component level error ($3.09 < 7.52$ for θ and $0.27 < 6.36$ for β). A similar effect is seen in the 10-dimensional data.

The ability to mask off certain components is useful. For instance, $|K| = 100$ may be a reasonable domain size, but items will often have far fewer active skills, *e.g.* Pardos *et al.* [7] used a question-set for high-school mathematics with $|K| = 105$, but a maximum of three skills per question. Masking is vital to represent such a domain as fixed-width vectors. Moreover, with Q-gates, the exact number and composition of skills per question need not be known: it can be learned during training. Hence the width of our embeddings need not exactly match the domain: if they are too wide, the Q-gates will trim excess components. We give a procedure to estimate $|K|$ next.

6.3 Dimensionality estimation

Although it is not possible to directly detect the dimensionality $|K|$ of a domain, there is a simple procedure to estimate it. Embeddings are trained across a span of candidate values $|K|_{cand}$ and the mean maximum accuracy for each $|K|_{cand}$

Figure 5: Dimensionality detection – candidate dimensions on x-axis, maximum accuracy for each fit on y-axis; ten runs per candidate, line plot shows mean maximum accuracy.

is calculated. Figure 5 shows the result of this process for a dataset with $|K| = 5$, $|S| = 1000$, $|I| = 100$. We plot candidates $|K|_{\text{cand}} \in \{1, 3, 5, 7, 10\}$ against the mean maximum accuracy (over 10 repetitions) of fit to the dataset. The peak at $|K|_{\text{cand}} = 5$ reveals the true value of $|K|$.

7. FUTURE WORK

We are in the process of mining skills embeddings from a major online physics-teaching platform. We believe the embeddings discovered will reveal more about realistic dimensionality and skill composition, and help us to study changes in student ability over time. We also intend to report on the interpretability of embeddings by human experts.

8. CONCLUSION

This work introduces a new technique to mine SKILLS EMBEDDINGS – student and item vector representations based on the Multicomponent Latent Trait Model – using a neural network with complementary weights. This was applied to synthesised student activity datasets, to recover the original seed parameters. We were able to extract these parameters in moderately high-dimension data ($|K|=10$) even for small datasets (100 items, 1000 students).

We gave four desired characteristics for our embeddings: co-proximity of similar objects in vector space, growth of magnitude with skill, ability to model missing skills, and applicability in domains of unknown dimension. We showed our embeddings support all but the fourth, and gave a procedure to mitigate this. We introduced Q-GATES, a skill masking mechanism that boosts model fit for high dimensional domains with realistic constraints.

ABSTRACT

Grade prediction for future courses not yet taken by students is important as it can help them and their advisers during the process of course selection as well as for designing personalized degree plans and modifying them based on their performance. One of the successful approaches for accurately predicting a student's grades in future courses is Cumulative Knowledge-based Regression Models (CKRM). CKRM learns shallow linear models that predict a student's grades as the similarity between his/her knowledge state and the target course. A student's knowledge state is built by linearly accumulating the learned provided knowledge components of the courses he/she has taken in the past, weighted by his/her grades in them. However, not all the prior courses contribute equally to the target course. In this paper, we propose a novel Neural Attentive Knowledge-based model (NAK) that learns the importance of each historical course in predicting the grade of a target course. Compared to CKRM and other competing approaches, our experiments on a large real-world dataset consisting of ~ 1.5 grades show the effectiveness of the proposed NAK model in accurately predicting the students' grades. Moreover, the attention weights learned by the model can be helpful in better designing their degree plans.

Keywords

grade prediction, knowledge-based models, neural networks, attention networks, undergraduate education

1. INTRODUCTION

The average six-year graduation rate across four-year higher-education institutions has been around 59% over the past 15 years [9, 2], while less than half of college graduates finish within four years [2]. These statistics pose challenges in terms of workforce development, economic activity and national productivity. This has resulted in a critical need for analyzing the available data about past students in order to provide actionable insights to improve college student

graduation and retention rates.

One approach for improving graduation and retention rates is to help students make more informed decisions about selecting the courses they register for in each term, such that the knowledge they have acquired in the past would prepare them to succeed in the next-term enrolled courses. Polyzou *et al.* [15] proposed course-specific linear models that learn the importance (or weight) of each previously-taken term towards accurately predicting the grade in a future course. One limitation of this approach is that in order to make accurate predictions, the model needs to have sufficient training data for each (prior, target) pair. Morsy *et al.* [13] developed Cumulative Knowledge-based Regression Models (CKRM) that also build on the idea of accumulating knowledge over time. CKRM predicts a student's grades as the similarity between his/her knowledge state and the target course. Both a student's knowledge state and a target course are represented as low-dimensional embedding vectors and the similarity between them is modeled by their inner product. A student's knowledge state is implicitly computed as a linear combination of the so-called provided knowledge component vectors of the previously-taken courses, weighted by his/her grades in them. Though CKRM was shown to provide state-of-the-art grade prediction accuracy, it is limited in that it assumes that all historical courses contribute equally in estimating the student's grade in a future course. Intuitively, students take courses from different departments, and each course would require an acquisition of knowledge from a few other courses, with different weights.

Motivated by the success of neural attentive networks in different fields [7, 12, 6, 1, 20], in this paper, we improve upon CKRM by learning the different importance of previously-taken courses in estimating the grade of a future course. We leverage the recent advances in neural attentive networks to learn these different weights, by employing both softmax and sparsemax activation functions that output posterior probabilities, i.e., attention weights, for the prior courses. The sparsemax function has an additional benefit of truncating the small probability values to zero, assigning zero effect to the irrelevant prior courses when predicting a target course's grade.

The main contributions of this work are as follows:

1. We propose a Neural Attentive Knowledge-based model

Sara Morsy and George Karypis "Sparse Neural Attentive Knowledge-based Model for Grade Prediction" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 366 - 371

(NAK) for grade prediction that improves upon CKRM by employing the attention mechanism in neural networks to learn the different importance of the prior courses towards predicting the grades of target courses. To our knowledge, this is the first work to apply attentive neural networks to grade prediction.

2. We leverage the recent sparsemax activation function for the attention mechanism that produces sparse attention weights instead of soft attention weights.
3. We performed an extensive experimental evaluation on a real world dataset obtained from a large university that spans a period of 16 years and consists of ~ 1.5 grades. The results show that our proposed NAK model significantly improves the prediction accuracy compared to the competing models. In addition, the results show the effectiveness of the attention mechanism in learning the different importance of the previously-taken courses towards each target course, which can help in designing better degree plans and more informed course selection decisions.

2. DEFINITIONS AND NOTATIONS

Boldface uppercase and lowercase letters will be used to represent matrices and vectors, respectively, e.g., \mathbf{G} and \mathbf{p} . The i th row of matrix \mathbf{P} is represented as \mathbf{p}_i^T , and its j th column is represented as \mathbf{p}_j . The entry in the i th row and j th column of matrix \mathbf{G} is denoted as $g_{i,j}$. A predicted value is denoted by having a hat over it (e.g., \hat{g}).

Matrix \mathbf{G} will represent the $m \times n$ student-course grades matrix, where $g_{s,c}$ denotes the grade that student s obtained in course c , relative to his/her average previous grade. Following the row-centering technique that was first proposed by Polyzou *et al.* [15], we subtract each student's grade from his/her average previous grade, since this was shown to significantly improve the prediction accuracy of different models. As there can be some students who achieved the same grades in all their prior courses, and hence their relative grades will be zero, in this case, we assigned a small value instead, i.e., 0.01. This is to prevent a prior course from not being considered in the model computation. A student s enrolls in sets of courses in consecutive terms, numbered relative to s from 1 to the number of terms in he/she has enrolled in the dataset. A set $\mathcal{T}_{s,w}$ will denote the set of courses taken by student s in term w .

3. RELATED WORK

3.1 Grade Prediction Methods

Grade prediction approaches for courses not yet taken by students have been extensively explored in the literature [16, 17, 8, 18, 15, 13, 5]. In this section, we review some research in grade prediction that is most relevant to our work.

3.1.1 Course-Specific Regression Models (CSR)

A more recent and natural way to model the grade prediction problem is to model the way the academic degree programs are structured. Each degree program would require the student to take courses in a specific sequencing such that the knowledge acquired in previous courses are required for the student to perform well in future courses. Polyzou *et al.* [15] developed course-specific linear regression

models (CSR) that build on this idea. A student's grade in a course is estimated as a linear combination of his/her grades in previously-taken courses, with different weights learned for each (prior, target) course pair. For a student s and a target course j , the predicted grade is estimated as:

$$\hat{g}_{s,j} = cb_j + \sum_{i \in \mathcal{P}} w_{i,j} g_{s,i}, \quad (1)$$

where cb_j is the bias terms for course j , $w_{i,j}$ is the weight of course i towards predicting the grade of course j , $g_{s,i}$ is the grade of student s in course i , and \mathcal{P} is the set of courses taken by s prior to taking course j . To achieve high prediction accuracy, CSR requires sufficient training data for each (prior, target) pair, which can hinder these models from good generalization.

3.1.2 Cumulative Knowledge-based Regression Models (CKRM)

Morsy *et al.* [13] developed Cumulative Knowledge-based Regression Models (CKRM), which is also based on the fact that the student's performance in a future course is based on his/her performance in the previously-taken courses. It assumes that a space of knowledge components exists such that each course provides a subset of these components as well as requires the knowledge of some of these components from the student in order to perform well in it. The student by taking a course thus acquires its knowledge components in a way that depends on his/her grade in that course. The overall knowledge acquired by the student after taking a set of courses is then represented by a knowledge state vector that is computed as the sum of the knowledge component vectors of those courses, weighted by his/her grades in them. Let \mathbf{p}_i denote the provided knowledge component vector for course i . The knowledge state vector for student s at term t can be expressed as follows:

$$\mathbf{k}_{s,t} = \sum_{w=1}^{t-1} \xi(s, w, t) \sum_{i \in \mathcal{T}_{s,w}} \left(g_{s,i} \mathbf{p}_i \right), \quad (2)$$

where $g_{s,i}$ is the grade that student s obtained on course i , and $\xi(s, w, t)$ is a time-based exponential decaying function designed to de-emphasize courses that were taken a long time ago.

Given the student's knowledge state vector prior to taking a course and that course's required knowledge component vector, denoted as \mathbf{r}_j , CKRM estimates the student's expected grade in that course as the inner product of these two vectors, i.e.,

$$\hat{g}_{s,j} = cb_j + \mathbf{k}_{s,t}^T \mathbf{r}_j, \quad (3)$$

where cb_j is as defined in Eq. 1, and $\mathbf{k}_{s,t}$ is the corresponding knowledge state vector. These course-specific linear models are estimated from the historical grade data and can be considered as capturing and weighting the knowledge components that a student needs to have accumulated in order to perform well in a course.

3.2 Neural Attentive Models

Our work relies on the attention mechanism, which has been recently introduced in neural networks and was shown to improve the performance of different models and give better

explanations to the importance of different objects towards a target object [6, 20, 7, 3]. Our work leverages several advances in this area. The most commonly-used activation function for the attention mechanism is the softmax function, which is easily differentiable and gives soft posterior probabilities that normalize to 1. A major disadvantage of the softmax function is that it assumes that each object contributes to the compressed representation, which may not always hold in some domains. To solve this, we need to output sparse posterior probabilities and assign zero to the irrelevant objects. Martins *et al.* [11] proposed the sparsemax activation function, which has the benefit of assigning zero probabilities to some output variables that may not be relevant for making a decision. This is done by defining a threshold, below which small probability values are truncated to zero. We also leverage the controllable sparsemax activation function recently proposed by Laha *et al.* [10] that controls the desired degree of sparsity in the output probabilities. This is done by adding an L2 regularization term that is to be maximized in the loss function. This will potentially encourage larger probability values for some objects, moving the rest to zero.

4. PROPOSED MODEL

4.1 Motivation

Consider a sample student who is declared in a Computer Science major and is in his/her second or third year in college. Table 1 shows the set of prior courses that this student has already take and the set of courses that this student is planning on taking the next term. With CKRM (Section 3.1.2), all these prior courses would contribute equally to predicting the grade of each target course. However, we can see that, intuitively, from the courses' names, there are courses that are strongly related to each target course and other courses that are irrelevant to it. For instance, it is reasonable to expect that the Intermediate German II course is more related to the Intermediate German I course than any of the other courses that the student has already taken. Along the same lines, we expect that the Algorithms and Data Structures course is more related to other Computer Science courses, such as the Advanced Programming Principles and the Program Design and Development courses. Assuming equal contribution among these prior courses can hinder the grade prediction model from accurately learning the course representations, and hence lead to poor predictions.

4.2 Overview

In this work, we present our Neural Attentive Knowledge-based model, NAK, which predicts a students' grades in future courses by employing an attention mechanism on the prior courses. We use CKRM as the underlying model (see Section 3.1.2).

4.3 Attention-based Pooling Layer for Prior Courses

In order to learn the different contributions of the prior courses in estimating the student's grade in a future course, we can employ the CSR technique (see Section 3.1.1) that learns the importance of each prior course in estimating the grade of each future course. Thus, we would estimate a

knowledge state vector for each target course j , using the following equation:

$$\mathbf{k}_{s,t,j} = \sum_{w=1}^{t-1} \sum_{i \in \mathcal{T}_w} \left(a_{i,j} g_{s,i} \mathbf{p}_i \right), \quad (4)$$

where $a_{i,j}$ is a learnable parameter that denotes the attention weight of course i in contributing to student s 's knowledge state when predicting s 's grade in course j . Note that we have removed the time-decaying function $\xi(s, w, t)$ that was used in CKRM (see Eq. 2), since it would be implicitly included in the attention weights. However, this solution requires sufficient training data for each (i, j) pair in order to be considered an accurate estimation.

In order to be able to have accurate attention weights between all pairs of prior and target courses, even the ones that do not appear together in the training data, we propose to use the attention mechanism that was recently used in neural networks [1, 19]. The main idea is to estimate the attention weight $a_{i,j}$ from the embedding vectors for courses i and j .

In order to compute the similarity between the embeddings of prior course i and target course j , we use a single-layer perceptron as follows:

$$z_{i,j} = \mathbf{h}^T \text{RELU}(\mathbf{W}(\mathbf{q}_i \odot \mathbf{r}_j) + \mathbf{b}), \quad (5)$$

where $\mathbf{q}_i = g_{s,i} \mathbf{p}_i$ denotes the embedding of the prior course i , weighted by the student's grade in it, \odot denotes the Hadamard product, and $\mathbf{W} \in \mathcal{R}^{l \times d}$ and $\mathbf{b} \in \mathcal{R}^l$ denote the weight matrix and bias vector that project the input into a hidden layer, respectively, and $\mathbf{h} \in \mathcal{R}^l$ is a vector that projects the hidden layer into an output attention weight, where d and l denote the number of dimensions of the embedding vectors and attention network, respectively. RELU denotes the Rectified Linear Unit activation function that is usually used in neural attentive networks.

4.3.1 Softmax Activation Function

The most common activation function used for computing these attention weights is the softmax function [19]. Given a vector of real weights \mathbf{z} , the softmax activation function converts it to a probability distribution, which is computed component-wise as follows:

$$\text{softmax}_i(\mathbf{z}) = \frac{\exp(z_i)}{\sum_j \exp(z_j)}. \quad (6)$$

We will refer to the NAK model that uses the softmax activation function as **NAK(soft)**.

4.3.2 Sparsemax Activation Function

Although the softmax activation function has been used to design attention mechanisms in many domains [14, 1, 6, 12, 7], we believe that using it for grade prediction is not optimal. Since a student enrolls in several courses, and each course requires knowledge from one or a few other courses, we hypothesize that some of the prior courses should have no effect, i.e., zero attention, towards predicting a target course's grade. We thus leverage a recent advance, the sparsemax activation function [11], to learn sparse attention weights. The idea is to define a threshold, below

Table 1: Sample of prior and target courses for a Computer Science student at University X.

Prior Courses	Target Course
Calculus I, Beginning German, Operating Systems, Intermediate German I, University Writing, Introductory Physics, Peotics in Film, Program Design & Development, Philosophy, Linear Algebra, Internet Programming, Stone Tools to Steam Engines, Advanced Programming Principles, Computer Networks	Intermediate German II
	Probability & Statistics
	Algorithms & Data Structures

which small probability values are truncated to zero. Let $\Delta^{K-1} := \{\mathbf{x} \in \mathbb{R}^K | \mathbf{1}^T \mathbf{x} = 1, \mathbf{x} \geq \mathbf{0}\}$ be the $(K-1)$ -dimensional simplex. The sparsemax activation function tries to solve the following equation:

$$\text{sparsemax}(\mathbf{z}) = \underset{\mathbf{x} \in \Delta^{K-1}}{\operatorname{argmin}} \|\mathbf{x} - \mathbf{z}\|^2, \quad (7)$$

which, in other words, returns the Euclidean projection of the input vector \mathbf{z} onto the probability simplex.

In order to obtain different degrees of sparsity in the attention weights, Laha *et al.* [10] developed a generic probability mapping function for the sparsemax activation function, which they called **sparsegen**, and is computed as follows:

$$\text{sparsegen}(\mathbf{z}; \gamma) = \underset{\mathbf{x}}{\operatorname{argmin}} \|\mathbf{x} - \mathbf{z}\|^2 - \gamma \|\mathbf{x}\|^2, \quad (8)$$

where $\gamma < 1$ controls the L2 regularization strength of \mathbf{x} . An equivalent formulation for sparsegen was formed as:

$$\text{sparsegen}(\mathbf{z}; \gamma) = \text{sparsemax}\left(\frac{\mathbf{z}}{1-\gamma}\right), \quad (9)$$

which, in other words, applies a temperature parameter to the original sparsemax function. Varying this temperature parameter can change the degree of sparsity in the output variables. By setting $\gamma = 0$, sparsegen becomes equivalent to sparsemax. We will refer to the NAK model that uses the sparsegen activation function as **NAK(sparse)**.

4.4 Prediction

NAK then predicts the grade for student s in course j that he/she takes at term t as:

$$\hat{g}_{s,j} = cb_j + \mathbf{k}_{s,t,j}^T \mathbf{r}_j. \quad (10)$$

4.5 Optimization

We use the mean squared error (MSE) loss function to estimate the parameters of NAK. We minimize the following regularized RMSE loss:

$$L = -\frac{1}{2N} \sum_{s,c \in \mathbf{G}} (g_{s,c} - \hat{g}_{s,c})^2 + \alpha \|\Theta\|^2, \quad (11)$$

where N is the number of grades in \mathbf{G} . The hyper-parameter α controls the strength of L2 regularization to prevent overfitting, and $\Theta = \{\{\mathbf{cb}\}, \{\mathbf{p}_i\}, \{\mathbf{r}_i\}, \mathbf{W}, \mathbf{b}, \mathbf{h}\}$ denotes all trainable parameters of NAK.

The optimization problem is solved using AdaGrad algorithm [4], which applies an adaptive learning rate for each parameter. It randomly draws mini-batches of a given size from the training data and updates the related model parameters. The source code can be found here: <https://urlzs.com/iH8G>.

5. EVALUATION METHODOLOGY

5.1 Dataset

The data used in our experiments was obtained from the University of Minnesota (UMN), which includes 96 majors from 10 different colleges, and spans the years 2002 to 2017. At the University, the letter grading system used is A–F, which is converted to the 4–0 scale using the standard letter grade to GPA conversion. We removed any grades that were taken as pass/fail. The final dataset includes $\sim 54,000$ students, 5,800 courses, and 1,450,000 grades in total.

5.2 Generating Training, Validation and Test Sets

At UMN, there are three terms, Fall, Summer and Spring. We used the data from 2002 to Spring 2015 (inclusive) as the training set, the data from Spring 2016 to Fall 2016 (inclusive) as the validation set, and the data from Summer 2016 to Summer 2017 (inclusive) as the test set. For a target course taken by a student to be predicted, that student must have taken at least four courses prior to the target course, in order to have sufficient data to compute the student's knowledge state vector. We excluded any courses that do not appear in the training set from the validation and test sets.

5.3 Comparison Methods

We compared the performance of our NAK model against the following grade prediction approaches:

1. **Matrix Factorization (MF):** This approach predicts the grade for student s in course i as:

$$\hat{g}_{s,i} = \mu + sb_s + cb_i + \mathbf{u}_s^T \mathbf{v}_i, \quad (12)$$

where μ , sb_s and cb_i are the global, student and course bias terms, respectively, and \mathbf{u}_s and \mathbf{v}_i are the student and course latent vectors, respectively. We used the squared loss function with L2 regularization to estimate this model.

2. **KRM(sum):** This is CKRM the method described in Section 3.1.2.
3. **KRM(avg):** This is similar to the KRM(sum) method, except that the prior courses' embeddings are aggregated with mean pooling instead of summation. It was shown in later studies, e.g. [17], that it performs better than KRM(sum).

We implemented KRM(sum) and KRM(avg) with a neural network architecture and optimization similar to that of NAK.

Table 2: Comparison between the baseline and proposed models.

Model	Parameters					RMSE	PTA0	PTA1	PTA2
MF	16	1E-04	1E-02	–	–	0.724	25.7	58.6	79.5
KRM(sum)	32	1E-07	7E-04	0.3	–	0.584	32.6	70.1	87.7
KRM(avg)	32	1E-07	7E-04	0.0	–	0.584	34.9	70.6	87.7
NAK(soft)	32	1E-07	7E-04	3	–	0.589 (–0.9%)	35.3† (1.1%)	71.8 (1.7%)	88.0† (0.3%)
NAK(sparse)	32	1E-07	7E-04	4	0.5	<u>0.574</u> †‡ (1.7%)	<u>35.3</u> † (1.1%)	<u>72.1</u> (2.1%)	<u>88.7</u> † (1.1%)

The Parameters columns denote the following model parameters that were selected: for MF, the parameters are: the number of latent dimensions, the L2 regularization parameter, and the learning rate; for KRM(sum) and KRM(avg), the parameters are: the embedding size for courses, the L2 regularization parameter, the learning rate, and the time-decaying parameter λ ; for NAK, the parameters are: the embedding size for courses, the L2 regularization parameter, the learning rate, and the number of latent dimensions for the MLP attention mechanism; and for NAK(sparse), the last parameter denotes the L2 regularization parameter γ for the sparsegen activation function. Underlined entries represent the best performance in each metric. The † and ‡ symbols are used to denote results that are statistically significant over the best performing baseline metric, and NAK(soft), respectively, using the Student’s paired t -test with a p -level < 0.1 . Numbers in parentheses denote the percentage of improvement over the best baseline value in each metric.

5.4 Model Selection

We performed an extensive search on the parameters of the proposed and baseline models to find the set of parameters that gives us the best performance for each model.

For all proposed and competing models, the following parameters were used. The number of latent dimensions for course embeddings was chosen from the set of values: {8, 16, 32}. The L2 regularization parameter was chosen from the values: {1e-5, 1e-7, 1e-3}. Finally, the learning rate was chosen from the values: {0.0007, 0.001, 0.003, 0.005, 0.007}. For the proposed NAK models, the number of latent dimensions for the MLP attention mechanism was selected in the range [1, 4]. For KRM(sum) and KRM(avg), the time-decaying parameter λ was chosen from the set of values: {0, 0.3, 0.5, 0.7, 1.0}.

The training set was used for estimating the models, whereas the validation set was used to select the best performing parameters in terms of the overall MSE of the validation set.

5.5 Evaluation Methodology and Metrics

The grading system used by the University uses a 12 letter grade system (i.e., A, A–, B+, ... F). We will refer to the difference between two successive letter grades (e.g., B+ vs B) as a *tick*. We converted the predicted grades into their closest letter grades. We assessed the performance of the different approaches based on the Root Mean Squared Error (RMSE) as well as how many ticks away the predicted grade is from the actual grade, which is referred to as *Percentage of Tick Accuracy*, or PTA. We computed the percentage of grades predicted with no error (zero tick), within one tick, and within two ticks, which will be referred to as PTA0, PTA1, and PTA2, respectively.

6. EXPERIMENTAL RESULTS

6.1 Performance of the Proposed Models

Table 2 shows the performance of our proposed models. Using the sparsegen activation function instead of the softmax activation function improves the prediction accuracy, with a statistically significant improvement. This shows that using the sparsegen activation function to output sparse attention weights for the prior courses achieves better prediction accuracy than producing soft probabilities for all of them. This is expected, since the student’s prior courses may not be all relevant to the target course, as illustrated in Table 1.

6.2 Performance against Competing Methods

Table 2 also shows the performance of the competing models. Among the baseline methods, both KRM(sum) and KRM(avg) outperform MF. KRM(avg) outperforms KRM(sum) in PTA0 and PTA1. Both NAK(soft) and NAK(sparse) outperform all baseline methods. Even though the RMSE results of NAK(soft) is worse than these of the KRM variants, it achieved $\sim 1\%$, $\sim 2\%$ and 0.5% more accurate predictions within no, one, and two tick errors, respectively. Among all baseline and proposed methods, our NAK(sparse) model outperforms all baseline methods significantly, with achieving $\sim 2\%$ lower RMSE, and $\sim 1\%$ more accurate predictions within two ticks than KRM(avg). This shows that using the attention-based pooling layer on the prior courses to accumulate them can better predict the grades of students in their future courses.

6.3 Qualitative Analysis on the Prior Courses Attention Weights

Recall the motivational example for the Computer Science student, discussed in Section 4.1. This student had a set of prior courses and three target courses that we would like to predict his/her grades in (See Table 1). Using KRM(sum) or KRM(avg), all the prior courses would contribute equally to the prediction of each target course. Using our proposed NAK(sparse) model, the attention weights for the prior courses with each target course are shown in Table 3¹.

We can see that, using the sparsegen activation function, only a few prior courses are selected with non-zero attention weights, which are the most relevant to each target course.

For the Intermediate German II course, we can see that the student’s grade in it is most affected by two courses: the Intermediate German I course, and the University Writing course. The Intermediate German I course is listed as a pre-requisite course for the Intermediate German II course. Though the University Writing course is not listed as a pre-requisite course, after further analysis, we found out that the Intermediate German II course requires process-writing essays and are considered part of the grading system. Though the German courses are not part of the student’s degree program, and are taken by a small percentage of Computer

¹These results were obtained by learning NAK models to estimate the actual grades and not the row-centered grades. Also, we used $\mathbf{q}_i = \mathbf{p}_i$ in Eq. 5. This allowed us to get more interpretable results.

Table 3: The attention weights of the prior courses with each target course learned by NAK(sparse) for the sample student from Table 1.

Prior Courses	Target Course
Intermediate German I: 0.6980 , University Writing: 0.3020	Intermediate German II
Calculus I: 0.4737 , Physics: 0.3794 , Program Design & Development: 0.0717 , Operating Systems: 0.0497 , Computer Networks: 0.0255	Probability & Statistics
Operating Systems: 0.2927 , Advanced Programming Principles: 0.2582 , Linear Algebra: 0.2313 , Physics: 0.2178	Algorithms & Data Structures

Prior courses are sorted in non-increasing order w.r.t. to their attention weights with each target courses for clarity purposes.

Science students, our NAK model was able to learn accurate attention weights for them.

The other two target courses, Probability and Statistics, and Algorithms and Data Structures, have totally different prior courses with the largest attention weights, which are more related to them.

These results illustrate that our proposed NAK model was able to uncover the listed as well as the hidden/informal pre-requisite courses without any supervision given to the model.

7. CONCLUSION

In this work, we presented a method to improve the grade prediction accuracy, by learning the weights of the prior courses towards predicting the grade of each target course. To this end, we employed the attention mechanism on the prior courses that learns the different contributions of these courses towards each target course. We employed both a softmax and a sparsemax activation function that produce soft and sparse attention weights, respectively. The proposed models are able to capture the listed as well as the hidden pre-requisite courses for the target courses, which can be better used to design better degree plans. Our experiments showed that our models significantly outperformed the competing methods, indicating the value of the attention mechanism on the prior courses.

ABSTRACT

In this study, we fitted a mixed-effects nonlinear continuous-time mutualism model of skill development proposed by van der Maas et al. (2006) to naturally collected irregularly spaced time series data from an online adaptive practice system for mathematics called Math Garden. Results showed that the mutualism model provided a better fit to the data than a g -factor model. The paper illustrates continuous-time modeling of irregularly-spaced multivariate time series data that are increasingly prevalent in modern learning systems.

Keywords

mutualism model, continuous-time model, mixed-effects model

1. INTRODUCTION

For the past century, generations of researchers have continued to pursue explanations for the consistent positive correlations between diverse sets of cognitive ability tests, known as *the positive manifold* [25, 29]. Heated debates went on about whether there is a potential biologically based g -factor that causes the development of general intelligence as well as the positive manifold [26, 7, 27, 11, 9]. Although researchers have not reached consensus, there is a shift from conceptualizing cognitive development as merely reflective, as in factor analysis, to thinking of it as formative [2, 14, 27]. In a formative model, the positive manifold is an emergent property that results from within-person changes and connections over time. This ontological stance implies that research needs to focus on understanding the causal relationships that underlie cognitive development to guide effective efforts to predict and intervene in students' learning.

Lu Ou, Abe Hofman, Vanessa Simmering, Timo Bechger, Gunter Maris and Han van der Maas "Modeling person-specific development of math skills in continuous time: New evidence for mutualism" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 372 - 377

Various mathematical representations encompassing continuous and discrete variables have been proposed to describe the mechanistic changes and sources of individual differences in cognition [28, 9, 32, 21]. From a developmental perspective, cognitive abilities develop as a dynamic system with reciprocal interactions between the elements of the system causing the developmental pathways of each of the elements [29]. In the *Mutualism* model of intelligence, elements of a system interact with each other in a collaborative way to achieve mutual benefits. This provides an alternative explanation for the positive manifold, other than the g -factor approach, and only requires sparse, weak, and even some negative interactions to produce positive correlations [28].

In the current study, we take advantage of massive time series data collected with an online learning environment for mathematics [12] and propose a method to fit the mutualism model to this dataset. We aim to examine potential reciprocal interactions of mathematical skills in two domains — counting and addition — in children's learning and practicing mathematics online. We build a model that takes into account individual differences in the learning processes by allowing individuals to start in different positions and by including random effects in key parameters of an otherwise group-based mutualism model. Note that this is the first application of the nonlinear mutualism differential equation model to empirical data, providing an evaluation of how well the theoretical account proposed by van der Maas et al. [29] can capture changes in children's mathematical skill development over time. In addition, we pioneer the use of continuous-time models to analyze irregularly-spaced data that arise when students use educational technology in realistic settings, and show that the estimation framework implemented in the *dynr* R package [19, 20] can handle nonlinear equations and mixed effects that explain both between-person and within-person differences.

In summary, the contribution of the work is three-fold: 1) providing new evidence of reciprocal interactions in mathematics skill development as a pioneer in fitting the nonlinear mutualism model to empirical data; 2) presenting a way to

analyze the irregularly spaced multivariate time series data commonly seen in learning systems; and 3) demonstrating the use of state-space approaches in estimating parameters of mixed-effects dynamic models.

In the following sections, we first explain the mathematical model we use to characterize the learning processes, and the estimation procedure. We then present how the empirical data in the current study were collected, and the sample characteristics. The paper ends with a discussion of the results and their implications for education.

2. THE MUTUALISM MODEL

In biology, the term *Mutualism* is used for a relation between species populations where different species organically interact with each other to maintain sustainable growth [1]. Biologists routinely use the Lotka-Volterra model [16, 30] to study the dynamics of such relations, which inspired van der Maas and colleagues [29] to propose the same model, referred to as the mutualism model, to study the dynamics of cognitive development, where elements of a cognitive system interact with each other to achieve mutual benefit.

2.1 The Lotka-Volterra Model

Mathematically, the mutualism model can be expressed using generalized N-subject Lotka-Volterra equations as

$$\begin{aligned} d\mathbf{x}(t) &= \mathbf{F}(\mathbf{x}_1(t), \mathbf{x}_2(t), \dots, \mathbf{x}_N(t))dt \\ &= \left[\rho_i x_i(t) \left(1 - \frac{x_i(t) + \sum_{j \neq i} a_{ij} x_j(t)}{K_i} \right) \right] dt, \end{aligned} \quad (1) \quad (2)$$

where $i, j = 1, 2, \dots, N$ indicates different elements of a dynamic system, and t is continuous time. Here, the elements are the counting and addition skills. The differential of vector $\mathbf{x}(t)$ with respect to t denotes the change in $\mathbf{x}(t)$ within an infinitely small time interval.

The model assumes logistic growth. The ρ_i are growth parameters that determine the steepness of the logistic growth function associated with each $x_i(t)$, and the K_i are the carrying capacity parameters that represent the limited resources in the system, such as limited attention and working memory one can allocate in learning. The a_{ij} are interaction parameters that specify the relations between each pair of x_i and x_j in development. With all $a_{ij} = 0$, the change of the latent variable $x_i(t)$ follows a simple logistic curve that converges to an equilibrium state of K_i , regardless of its starting position. The system is collaborative if the Jacobian matrix $\frac{\partial \mathbf{F}}{\partial \mathbf{x}}$ is positive definite, and is competitive otherwise. If, for all i , $x_i(t)$ and ρ_i only take positive values, then it is possible to show that as long as the combined consumption of resources $x_i(t) + \sum_{j \neq i} a_{ij} x_j(t)$ does not exceed the carrying capacity K_i , $x_i(t)$

will continue to increase to its equilibrium. Further, when the interaction parameters a_{ij} are negative (or $-a_{ij}$ are positive) for all $j \neq i$, $x_i(t)$ can develop even beyond the original carrying capacity K_i , as a benefit of the collaboration with the other processes. On the other hand, when the parameters $a_{ij}, j \neq i$ are positive, $x_i(t)$ can never reach the full potential K_i , as a loss due to competition. van der Maas and colleagues [29] showed that when $-a_{i,j}$ is positive and

less than 1, the mutualism model can result in the positive manifold.

2.2 State-space Representation

If we take into account individual differences in the mutualism model, as well as process noise and measurement errors¹ that may occur alongside the manifestation of the mutualism process, we obtain a state-space representation of the mutualism model:

$$d\mathbf{x}_s(t) = \mathbf{F}_s(\mathbf{x}_s(t))dt + d\mathbf{w}_s(t) \quad (3)$$

$$\mathbf{F}_s(\mathbf{x}_s(t)) = \begin{bmatrix} \rho_1 x_{1,s}(t) \left(1 - \frac{x_{1,s}(t) + a_{12} x_{2,s}(t)}{K_1 + b_{1,s}} \right) \\ \rho_2 x_{2,s}(t) \left(1 - \frac{x_{2,s}(t) + a_{21} x_{1,s}(t)}{K_2 + b_{2,s}} \right) \end{bmatrix} \quad (4)$$

$$\mathbf{y}_s(t_{s,k}) = \mathbf{x}_s(t_{s,k}) + \boldsymbol{\epsilon}_s(t_{s,k}), \quad (5)$$

$$\boldsymbol{\epsilon}_s(t_{s,k}) \sim N \left(\mathbf{0}, \boldsymbol{\Sigma}_\epsilon = \begin{bmatrix} \sigma_{\epsilon,1}^2 & 0 \\ 0 & \sigma_{\epsilon,2}^2 \end{bmatrix} \right), \quad (6)$$

where the subscript s indexes individuals, and $k = 1, 2, \dots, T_s$ indexes the k th discrete person-specific measurement occasions $t_{s,k}$. The vector $\mathbf{x}_s(t)$ contains the latent counting and addition skills $x_{1,s}(t)$ and $x_{2,s}(t)$ for an individual s , manifested as $\mathbf{y}_s(t_{s,k})$ in a measurement model with serially independent Gaussian measurement errors $\boldsymbol{\epsilon}_s(t_{s,k})$. The differential of $\mathbf{x}_s(t)$ is determined by the systematic dynamic functions $\mathbf{F}_s(\cdot)$ and the differential of process noise $\mathbf{w}_s(t)$ that follows a Wiener process (i.e., a continuous-time version of random walk, [10]), with a diffusion matrix $\mathbf{Q} = \begin{bmatrix} \sigma_{w,1}^2 & 0 \\ 0 & \sigma_{w,2}^2 \end{bmatrix}$. Person-specific random effects $\begin{bmatrix} b_{1,s} \\ b_{2,s} \end{bmatrix}$ are added to the carrying capacity parameters, and are assumed to follow a normal distribution with mean $\mathbf{0}$ and a covariance matrix of $\boldsymbol{\Sigma}_b = \begin{bmatrix} \sigma_{b,11}^2 & \sigma_{b,12}^2 \\ \sigma_{b,12}^2 & \sigma_{b,22}^2 \end{bmatrix}$.

The initial condition, or the distribution of the variables at the first available time point, of the dynamic process $\mathbf{x}_s(t_{s,1})$ is assumed to follow a multivariate normal distribution with mean $\begin{bmatrix} \mu_{1,1} \\ \mu_{1,2} \end{bmatrix}$ and variance $\begin{bmatrix} \sigma_{1,11}^2 & \sigma_{1,12}^2 \\ \sigma_{1,12}^2 & \sigma_{1,22}^2 \end{bmatrix}$.

2.3 An Alternative G-factor Model

In order to explore the fit of the mutualism model to empirical data compared to the g -theory, a comparable state-space

¹Process noise is distinct from measurement error in that the former is associated with random behavior in the underlying process, whereas the latter depends on the measurement process, device, and other environmental influences that may affect the accuracy of the measurements. In an educational context, a correct guess without knowing an item can be seen as a measurement error, while a child having a good or bad day could contribute to the process noise. Whereas measurement error does not influence growth at the next time point, the process noise does steer the dynamical system.

one-factor model without interactions can be developed as

$$dx_s(t) = \rho_1 x_s(t) \left(1 - \frac{x_s(t)}{K_1 + b_{1,s}}\right) + dw_s(t) \quad (7)$$

$$x_s(t_{s,1}) \sim N(\mu_{1,1}, \sigma_{1,11}^2), \mathbf{Q} = [\sigma_{w,1}^2], \mathbf{\Sigma}_b = [\sigma_{b,11}^2]$$

$$\mathbf{y}_s(t_{s,k}) = \begin{bmatrix} 1 \\ \lambda \end{bmatrix} x_s(t_{s,k}) + \boldsymbol{\epsilon}_s(t_{s,k}), \quad (8)$$

$$\boldsymbol{\epsilon}_s(t_{s,k}) \sim N\left(\mathbf{0}, \mathbf{\Sigma}_\epsilon = \begin{bmatrix} \sigma_{\epsilon,1}^2 & 0 \\ 0 & \sigma_{\epsilon,2}^2 \end{bmatrix}\right),$$

where the observed variables are linearly linked with the single latent variable through a loading matrix of $\begin{bmatrix} 1 & \lambda \end{bmatrix}^\top$.

3. ESTIMATION

To estimate the random effects in the models, we augmented the latent variables $\mathbf{x}_s(t)$ with random effects \mathbf{b}_s to yield a new latent variable vector, $\mathbf{x}_s^*(t) = [\mathbf{x}_s(t) \ \mathbf{b}_s]^\top$. We then modified the differential equations, the measurement model, and the initial condition to incorporate this change of $\mathbf{x}_s^*(t)$.

We used the dynr R package [19, 20] to estimate the parameters in the mixed-effects mutualism model, as well as the baseline g -factor model, by numerically optimizing an approximate log-likelihood function obtained as a by-product of the continuous-discrete extended Kalman filter [15]. Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) were constructed to compare models. Details of the estimation algorithms can be found in [4, 20].

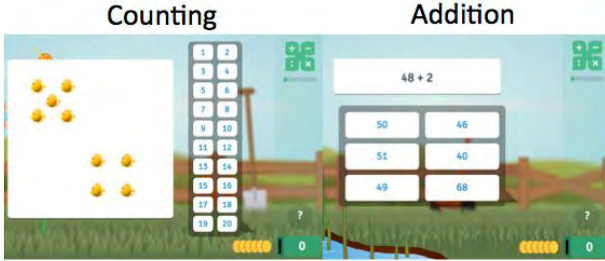

Figure 1: Screen shots of the counting and addition games in the Math Garden. Children give responses by clicking an option. The coins at the bottom disappear one per second, and reflect the scoring rule based on accuracy and response time.

4. EMPIRICAL STUDY

Here, we describe an application of the mutualism model.

4.1 Math Garden

We sampled data using a popular Dutch online adaptive practice and monitoring system called Math Garden [13]. The system consists of games that measure different mathematical skills, including counting and addition, as players practice their arithmetic skills through answering items. Figure 1 shows screen shots of two example items.

The system applies an explicit scoring rule for both speed and accuracy [17], visible to players as the number of coins they collect. For each item, a limit number of coins can be collected, and the number decreases by one at each additional second used to come up with the answer. In case of

a correct answer, the score equals the remaining time. If the answer is incorrect, the score is the negative remaining time. The scoring rule takes speed-accuracy trade-off into account, penalizes quick but incorrect answers, and encourages thoughtful responses.

Skill rating and item difficulty are estimated on-the-fly using the Elo-algorithm [6] which was originally developed for chess competitions between two players, and now has been adapted for pairing a player with an item [13]. The skill and difficulty estimates for a player and an item are updated at each “match” they are involved in, depending on the weighted difference between observed and expected correctness, the latter of which is entailed by the measurement model [17]. Evidence has shown high validity and reliability of the skill and difficulty estimates [13].

In the current study, our observed data are the continuous end-of-day skill ratings in different domains, rather than binary correctness for each item. Comparisons of Math Garden’s underlying measurement model [17] and the adapted Elo-algorithm [13] to other common models for binary responses in educational data mining — the Rasch model [23], additive factor models [3], performance factor analysis [22], and Bayesian knowledge tracing models [5] — are worth exploration, but beyond the scope of this paper.

4.2 Data Description

We selected a sample of children in grades 3–6, between the ages of 6 and 10 years old, who practiced counting and addition skills during at least 4 different months in the school year from September, 2016 to July, 2017, and had played at least 20 different days in each domain, with a minimum of 10 items per day. We excluded children whose parents indicated unwillingness to participate in Math Garden-related scientific research that was approved by the Ethics Committee of the psychology department of University of Amsterdam.

The resulting sample included a total of 2485 children, 51.07% male. The average age at which a child started to use Math Garden for practicing counting and addition during the school year was 7.23 years old ($SD = 1.03$). The original skill ratings could be negative, so we shifted them to the positive range by respectively adding 20 and 25 to the counting and addition scales. The over-time ebb-and-flow and variability of the skill ratings remain the same. From the second-by-second time stamps of the data points, we constructed continuous measures of time where each unit represents a week. Figure 2 shows the shifted skill ratings for three randomly selected individuals over time.

Distributions of the initial and ending skill ratings are plotted in Figure 3. At the first available time point for each individual, the counting skill ratings for all sampled children had a mean of 13.84 and a variance of 1.51, whereas the addition skill ratings had mean 12.94 and a larger variance of 10.56. At the last available time point for each individual, the ending counting estimates had a mean of 14.83 and variance of 1.49, while the ending addition estimates had a mean of 15.92 and variance of 9.05. Generally speaking, during the school year, more development is observed in the addition skill compared to the counting skill. There was more variability in children’s initial and ending addition skill ratings

Figure 2: Individual time series data of counting and addition skill ratings for three children.

than in the counting domain.

Figure 3: Histograms of the initial and ending skill ratings

The correlation between the initial addition and counting skill ratings was .73, and the correlation between the ending ratings was .79, confirming the positive manifold. Figure 4 shows the boxplot of within-person correlations between the skill ratings in the two domains. The mean of the within-person correlations was .55 ($SD = 0.38$). However, some negative values were observed at the significance level of 0.05 of the asymptotic p-values computed by the Hmisc R package [8]. For example, in Figure 2 the child with identification number 1344 had upward growth in the addition skill ratings and downward decline in the counting skill ratings. The downward decline may be due to an unexpected bump in the skill ratings that was higher than the child's equilibrium and hence resulted in a return to the equilibrium. Another possible explanation would be that, the child learned and practiced counting at school before addition, but forgetting took place as the child started to learn addition and practiced counting less. In such a case, there was a competition for attention and learning time between the skills in different domains, instead of a collaboration. Either case can be captured by the mutualism model.

The length of the individual time series of the counting skill ratings ranged from 20 to 177 days with a median of 29 days, and that of the addition skill ratings ranged from 20 to 192 days with a median of 42 days. The length of the interval between two time points represents the inactivity gap between two practice days of an individual for a mathematical skill, and ranged from 1 day to 18.29 weeks. The minimal gap length of a single time series had a median of 1 day across the sample in both domains, whereas the median maximum gap length was 4.86 weeks in the counting domain and 4 weeks in the addition domain. In Figure 5, the data of

Figure 4: A boxplot of the within-person correlations of the addition and counting skill ratings.

ten randomly selected individuals illustrate the irregularly-spaced measurement occasions, as well as the unbalanced practices in each domain on a single day and across time. The mutualism model assumes a continuous integrative process of change even though we do not have measurements of each skill at all times.

Figure 5: An illustration of the irregularly spaced time intervals of ten randomly selected individuals. Different colors represent the domains that an individual practiced during a specific day.

4.3 Empirical Results

The parameter estimates and model fit indices of both the mutualism model and the g -factor model were summarized in Table 1. All parameters were estimated to be significantly different from zero ($p < .05$). The estimates of the initial condition parameters ($\mu_{1,1}$, $\mu_{1,2}$, $\sigma_{1,1}^2$, $\sigma_{1,12}^2$, and $\sigma_{1,22}^2$) in both models were consistent with the sample mean and variance of the initial states. With lower AIC and BIC values, the mutualism model provided a better fit to the data compared to the g -factor model. Figure 6 shows the fit of the mutualism model to the observed data of four randomly selected individuals. The fitted trajectories were able to capture the changes of the observed paths for the individuals in both domains, suggesting a decent fit of the model to the data. In the mutualism model, the steepness parameters ρ_1 and ρ_2 were estimated to be close to zero, indicating that the overall development in skills was small and slow. The group-level equilibrium states K_1 and K_2 , for when there was no interaction between the processes, were estimated to about 10, but individual differences captured by the random effects b_1 and b_2 contribute to an estimated co-variance of $\begin{bmatrix} 1.04 & 0.09 \\ 0.09 & 1.06 \end{bmatrix}$. Estimates of the interaction parameters a_{12} and a_{21} were found to be significantly negative, so the inter-

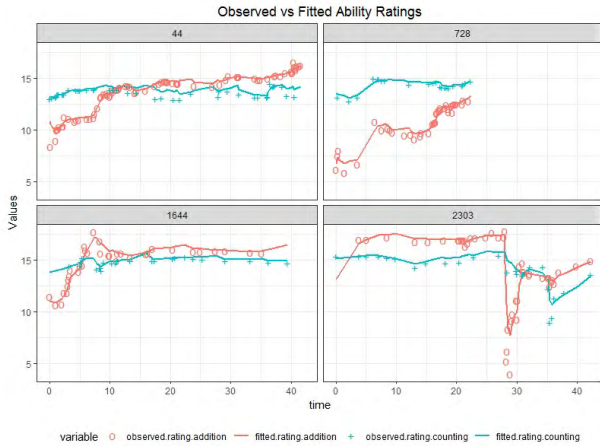

Figure 6: Observed and fitted skill ratings from the mutualism model.

actions between counting and addition ratings had a positive effect on their level changes. These results indicated that counting and addition skills collaborate, instead of competing, to form a positive manifold in the long run.

In summary, we have found beneficial interactions between children’s addition and counting skill ratings as being better at one skill helps being better at the other. The mutualism model was a better fit to the data than the g -factor model. Individual differences are present in the data in both starting positions of the change trajectories and key model parameters that represent limited resources in the system, providing potential evidence for both the g -theory and the mutualism model of general intelligence, according to [29]. We concur with van de Maas and colleagues (2006) that individual differences cannot be ignored in educational applications.

ferences cannot be ignored in educational applications.

5. CONCLUSIONS

In this paper, we presented a state-space expression of the continuous-time mutualism model proposed by [29] where individual differences, process noise, and measurement errors were taken into account. The mutualism model allowed us to tackle the underlying mechanism of the skill development from a micro perspective. We fitted the theoretical model to empirical data naturally collected online in authentic educational settings. Results showed that improvement in addition skill could positively influence the development in the counting domain, and vice versa. The better fit of the mutualism model to the data compared to the g -factor model suggested that the collaboration between the counting and addition skills in their co-development served as a better interpretation of the observed positive manifold.

The characteristics of the time series data in the current study are not uncommon in education as digital technology has transformed our way of collecting data about learning. The paper illustrates one way to fit dynamic models to the multivariate noisy irregularly spaced data that are rich in our real life. We appreciate the potential to apply the current method to different learning data to improve our understanding of cognitive and non-cognitive developments.

Nevertheless, this work has limitations that future work should aim to overcome. First, only two variables were considered in the current sample, while the mutualism model could be extended to multiple dimensions. The estimation algorithm is well suited for multivariate time series data, but the interpretation of the multivariate model can become complicated. Second, the estimation framework permits only a limited number of random effects in the current study [18]. In addition to the two carrying capacity parameters, one may be interested in adding random effects in the interaction parameters because of the potential competition between skills under time and attention constraints as we discussed above. The limitation of the estimation framework may be circumvented by utilizing sampling-based algorithms although they may be computationally heavy.

The fitting of the model to the data does not exclude other probable ways of interpreting cognitive development. Intervention studies with deliberate experimental designs are needed to establish causal relations in a dynamic system. These interventions may take the form of randomized assignment of skills to practice, for example, with groups of students assigned to practice only counting or only addition, but with progress measured on both skills after some period of practice. The cross-skill influence of practice can then be evaluated relative to practiced skill improvement.

Future work should also aim to evaluate how the mutualism account of skill development relates to other findings in education. For example, evidence suggests that interleaving practice on different problem types produces more robust learning and generalization than does blocking practice by problem type [31, 24]. It is possible that some of the benefit from interleaving relates to mutualism, with practice from different problem types influencing the development of the other skills.

ABSTRACT

Games in service of learning are uniquely positioned to offer immersive, interactive educational experiences. Well-designed games build challenge through a series of well-ordered problems or activities, in which perseverance is key for working through in-game failure and increasing game difficulty. Indeed, persistence through challenges during learning is beneficial not just in games but in other contexts as well, with grit and perseverance positively associated with academic performance and learning outcomes. However, recent studies suggest that not all persistence is positive, suggesting that many students end up “wheel-spinning”, spending considerable time on a topic without achieving mastery. Thus, it is vital to differentiate productive and unproductive persistence in order to understand emergent student progress, particularly in the context of learning games and personalized learning systems, in which individual pathways differ greatly based on student needs. Leveraging Educational Data Mining methods, this study builds a detector of wheel-spinning behavior (differentiated from productive persistence) in an adaptive, game-based learning system. With the ability to predict unproductive persistence early, this detection model can be used to intelligently adapt to students needing further support in-system, as well as informing in-person intervention in a classroom setting—thus supporting a personalized, engaging learning experience in both formal and informal learning environments.

Keywords

Behavior detection, predictive modeling, productive persistence, wheel-spinning, educational games, personalized learning

1. INTRODUCTION

Games as learning vehicles can offer engaging, interactive experiences in which the player has agency in exploring and solving well-ordered problems or challenges in a learner-responsive environment [1, 2]. Well-designed games seamlessly embed meaningful instruction in authentic, narrative-driven

learning contexts (with the potential to assess learning in the natural progression of play [3]). As such, they have the ability to optimize learner motivation and learning trajectories without removing the experience of personal discovery [4]. By nature, games encourage discovery of an underlying rule system through boundary testing, making experimentation and failure a core part of play progression [5]. In this sense, moving through in-game failure and challenge with perseverance can be fundamental to the experience of learning in games (e.g. [6, 7]). Hence, games offer a particularly relevant context for productive persistence or grit—the ability to steadily maintain an action or complete a task despite failure or adversity (cf. [8]). Indeed, keeping players in a “flow” state of persistence [9] through a series of challenges of increasing difficulty is key to the design of “good” games, particularly in educational contexts [10]. Recent research suggests these qualities in games support student growth in areas such as academic learning, socio-emotional skills, and creative problem solving (e.g. [11, 12, 13, 14]).

Indeed, persevering through challenges during learning is beneficial not just in games but in other contexts as well. From undergraduates to military cadets to Spelling Bee competitors, findings suggest that persistence forecasts strong performance in rigorous, achievement-based learning contexts [15]. In many cases, persistence is also associated with academic achievement [16], creativity [17], and long-term outcomes like earnings and later schooling [18].

However, recent research suggests that not all persistence is positive. “Wheel-spinning” is a form of unproductive effort, where students spend too much time struggling to learn a topic without achieving mastery [19]. Wheel-spinning behaviors have been associated with reduced motivation [20] and avoiding asking for help when needed [21]. In fact, recent empirical investigation has demonstrated that wheel-spinning can be differentiated from productive persistence in an intelligent tutoring system, in real-time, determining during problem-solving whether a student’s persistence will be productive [22]. Making this type of differentiation could also be valuable in learning games contexts. Persistence is important in games just as in other settings [23], with evidence suggesting that persisting unproductively in games can be a highly frustrating experience (e.g. [24]). Since challenge and problem solving are often core components of learning experiences, particularly in game-based environments, it becomes increasingly important to differentiate productive persistence (e.g. grit) from unproductive persistence (e.g. wheel-spinning) in the context of play. This differentiation could be used to offer different pathways to students based on real-time performance.

V. Elizabeth Owen, Marie-Helene Roy, K. P. Thai, Vesper Burnett, Daniel Jacobs, Eric Keylor and Ryan S. Baker “Detecting Wheel Spinning and Productive Persistence in Educational Games” In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 378 - 383

There is evidence that this type of modeling is feasible; related game-based research has shown that the same surface behavior in games can have different meanings, with distinction of productive vs unproductive failure in a games context (cf. [25]).

In this study, we empirically investigate wheel-spinning vs productive persistence in an adaptive, game-based learning system for early childhood math skills called *Mastering Math*. Specifically, we use predictive analytics to infer whether a student is engaging in wheel-spinning or productive persistence in *Mastering Math*. This detection model can be used to intelligently adapt to students needing further support in-system, as well as informing in-person intervention in a classroom setting—thus supporting a personalized learning experience in both formal and informal learning environments.

2. METHODS AND DATA COLLECTION

2.1 Game-based Learning Content

Mastering Math (MM) is a game-based adaptive learning system designed to help elementary age children build a strong understanding of fundamental number sense and operations, ranging from counting to 10 to adding and subtracting three-digit numbers using the standard algorithm. The app constitutes approximately 130 games, covering number sense and operations concepts and skills for pre-kindergarten through second grade. Each individual game maps to a learning objective, and is supported by an interactive instruction level, as well as several layers of scaffolding and feedback. In addition, the game system as a whole uses cohesive narrative and interactive characters (embedded at the level of individual games) to support student engagement with the learning world. Adaptivity functions within individual games to provide scaffolding with each level of skill difficulty, between games to adjust to students' difficulty needs, and across the system to give players a customized pathway between skills based on performance. Assessment is embedded throughout the play experience, including game-based pretests and final assessment tasks at a granular skill level.

2.2 Experimental Design

In the fall of 2018, two research studies were conducted to evaluate the effectiveness of *MM* in preschool (Study 1) and kindergarten (Study 2) students. Students in both studies came from ethnically diverse, low-income, public school districts in Southern California.

Both studies employed a cluster-randomized trial design, in which half of the participating classrooms in each study were randomly assigned to use the *MM* app as part of their classroom instruction (treatment group), while the other half used business-as-usual mathematics instruction and materials (control group). The treatment group students (394 students in total, 146 from Study 1, 248 from Study 2) were asked to use *MM* in small group settings for 15 minutes per day for three days per week, over a total of 12 weeks. After classroom implementation, overall usage averaged 5.6 hours in Study 1, and 5.22 hours in Study 2. Both treatment and control groups received a paper-and-pencil standardized assessment of early mathematics performance before and after the implementation of *MM*.

2.3 Event-stream Data Collection

Event stream data were collected using a learning game data framework based on ADAGE (Assessment Data Aggregator for

Game Environments; [26]), focusing on key learning mechanic milestones as context for performance information and results, as well as comprehensive coverage of player interaction and system feedback (e.g. [27]). These milestones are called *units*, and represent repeating progress mechanics through the learning game. Generally, students can play many games in the system (each of which corresponds with a mathematics skill), and each game contains multiple levels of difficulty. Thus, a larger unit of play is a game, and within a game a student can play one level (or activity) at a time. Each activity is built to support and assess knowledge of an individual math skill. All unit starts and ends are marked in the data, and all player interactions, system feedback, and results are recorded in the *context* of the active units at the time of the event. For example: if a student taps on the screen, we capture the basic x,y coordinate, the object being tapped (if applicable), and the units that were active during the tap (e.g. which game, activity and round the player was in when the event fired). In-game performance information (e.g. *result* or score) is embedded at the unit level, recorded at the end of applicable rounds and activities. In terms of raw *player interaction*, data collected consists of taps and drags. System feedback, also called *system events*, consists mainly of the game communicating with the player in giving formative feedback. This includes tutorial prompts, instructional input, and inactivity prompts (given if students have not interacted with the screen in 30 seconds). Additionally, every log file event is seeded with metadata such as student ID, timestamp, and session ID. Data structured in this fashion (Figure 1) allows for a comprehensive event-stream record that is labeled consistently across the system—which currently contains over 130 activities—all aligned with learning design for interpretability, a key element of viable data use for feature engineering and analysis.

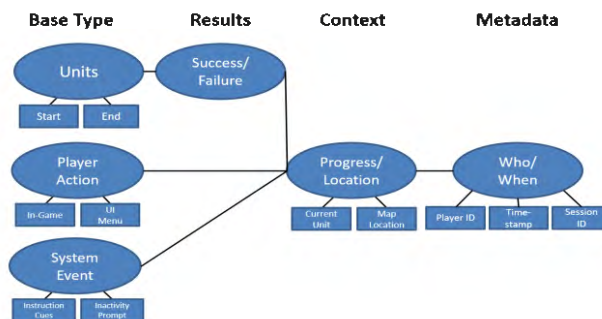

Figure 1. A simplified view of *MM*'s log file data schema.

2.4 Behavior Detection

To investigate player patterns of wheel-spinning in *Mastering Math*, prediction modeling was used to build a behavior detector (i.e. model of student behavior), an automated model that can infer from log files whether a student is behaving in a certain way (e.g. [28]). These models can be employed to detect a variety of important aspects of the learner and his/her performance, including student learning, strategy, and engagement (e.g. [29, 12, 30, 31]). To train the predictive model, detectors often leverage human judgment of student behavior, in a process where behavior labels derived from human judgement are used to train and validate models, which can then automatically detect the target behavior in the larger event-stream. In this case, once the initial student interaction with a digital learning environment is captured, the analysis process includes: 1) distilling data features potentially relevant to the behavior construct; 2) identifying

instances of the behavior through human evaluation; and 3) predictive modeling with the synchronized log file data.

Throughout these phases of analysis, a critical element of the data mining approach is emphasis on the event-stream trajectories that emerge in relationship to the behavior. With this detector study, each student's event-stream play patterns were observed and coded individually for emergent wheel-spinning behavior. Specific actions and click-stream interactions then emerged as evidence of wheel-spinning through the prediction algorithm's variable selection processes. Thus, player choices and interactions characteristic of wheel-spinning were derived from the larger event-stream data flow in the analysis process detailed below.

2.4.1 Feature Distillation

In this analysis, data features were distilled from *MM* event-stream data based on play across the entire system, then refined along themes of progression and performance. These organizing themes help capture student trajectories across the system for behavior detection, particularly since student progress and failure/success are central to the target constructs of wheel-spinning and productive persistence.

Using the learning progress mechanics, or units (i.e. games or activities) from the event-stream data schema, data features were organized based on performance within each unit, as well as measures of progression (e.g. time elapsed, number of activities completed, number of games activated, etc.). (For reference, when a game is activated, it means that a student failed the associated pretest and that gameplay for that skill is now open.) Summary features were also created in parallel to the unit features, giving a sense of the overall trajectory of the player through the learning space. Since PreK and K students are in developing stages of cognition, additional features were engineered to represent age and elements of motor skill (e.g. miss rate, or how often a student drags an object towards a target and misses). One view of selected event-stream features is given below (Table 1).

Table 1. Overview of selected event-stream features

	<i>Progression</i>	<i>Performance</i>
<i>Overall</i>	<ul style="list-style-type: none"> total duration in system (active play) total activities completed total activities started total games started miss rate student age 	<ul style="list-style-type: none"> % of skills mastered ratio of "boss" activities successfully passed* total # of skills (games) activated total skills mastered (games completed)
<i>Game</i>	<ul style="list-style-type: none"> game completion rate avg duration to game completion # of answers submitted per player per game # of activities completed within each game avg time elapsed between activities in the same game 	<ul style="list-style-type: none"> individual game status: <ul style="list-style-type: none"> - in-progress - passed game (skill completed) - struggling (fail states for 3 of the last 5 activities) - not started - pretest passed** - pretest failed % of started games successfully completed
<i>Activity</i>	<ul style="list-style-type: none"> activity completion rate avg activity duration # of hints given # of inactivity prompts # of tutorials accessed 	<ul style="list-style-type: none"> score progression to next level (pass/fail) # of rounds passed # of rounds failed # of rounds completed

*The "boss" activity is the most difficult assessment in a game

**Pretests are embedded at the game level to test prior knowledge

2.4.2 Behavior Coding of Wheel-spinning

For behavior detection, we focused on the construct of wheel-spinning, since the ability to flag this particular behavior held strong utility for enabling automated scaffolding in-system as well as in-person teacher intervention. Wheel-spinning is also an especially relevant focus for a game context—a medium in which boundary testing is an implicit norm [25], and differentiating real struggle from more productive forms of exploration and self-paced discovery can be valuable. *Mastering Math* games are sufficiently different from the intelligent tutoring systems, where wheel-spinning was initially studied, to require a different operationalization of wheel-spinning. In this context, we view wheel-spinning as connected to lower gameplay efficiency in the system, since wheel-spinning occurs when a great deal of effort yields very little progress [19]. To capture efficiency in an adaptive games context, in which every student has a different learning pathway, we designed a metric allowing efficiency to be standardized across players. This measure of learning efficiency was called *rate of mastery*, designed to measure the rate at which students were mastering math skills. This was calculated as the number of boss activities (the hardest assessment level in each math skill game) a student passed, divided by his/her total number of activities. This measure made sense as a progress-based metric, since performance on boss-level skill assessments is central to learning game progression. This ratio was ultimately calculated using data from both school studies. In the main behavior analysis, in accordance with the focus on wheel-spinning students and those persevering through difficulty, we concentrated on students in the lower two quartiles of *rate of mastery*.

As noted in Kai et al., 2018, we cannot assume that all lower efficiency students in the system are hopelessly struggling—on the contrary. Students who take their time to learn material, use self-paced progression, and achieve eventual success are likely to be demonstrating productive persistence. Determining whether a low-efficiency student is spinning their wheels or persisting productively is challenging. To differentiate these two groups, we started by leveraging human judgement on a per-student level to capture emergent patterns in the data. In particular, we chose to utilize the human capacity for pattern recognition and behavior evaluation (rather than an a priori rule-based approach), since the system is adaptive and no two students are likely to have the same path through the learning space.

Thus, the next step was to have human researchers observe a stream of student actions and identify the student's behavior (e.g. [32]). The human evaluation of student behavior establishes when the behavior occurred (which serves as the predicted variable). For coding of wheel-spinning behavior in this study, play visualization based on text replays were adopted for their efficiency and accuracy [33]. Text replays, based on recorded log file data, are a text-based representation of student action during a given period of time. Text replays have shown to be highly time-efficient and scalable [50], and almost as accurate for detecting student behavior as other methods such as live observation [34].

The variation on the text replay that we used—called a visual progress replay (VPR)—includes color coding of performance levels (in addition to text summaries) for greater ease of information processing (cf. [35]). This approach represents the same information as a text replay, but in a form that encodes information with color consistent with canonical visualization

techniques [36], and has previously been used to create detection models in related game-based learning research (e.g. [25]). Key features of the VPR included a visual display of game status, per student, across the system. This color-coded visual map showed whether each game was in-progress, completed (passed), in a struggle state (i.e. at least 3 non-passing scores within the last 5 activities), or not started. In addition, summary statistics per student were shown, such as number of activities completed in the system and time spent in total (Figure 2).

Figure 2. A sample portion of a VPR used for coding wheel-spinning, shown for a single student across the system.

We designed the replay's clip size to show one student's full system playthrough at a time, since we wanted to be able to detect a system-wide wheel-spinning state for each child. To capture the full trajectory of play, coding was done at the student level, labeling each student at the end of the study (week 12), in terms of whether a student was WS (wheel-spinning), P (productive persistence), and NA (not enough information). Within the lower efficiency group of students, WS captured a state of high effort but little progress, P fit with steady student progress, and NA was applied when there wasn't enough information (e.g. not enough time or activities in game to make a judgement). We included NA in this schema so that we could *derive* time and activity minimums for WS vs P differentiation through the predictor itself, rather than picking an arbitrary cutoff in excluding student data (such as, for instance, dropping all students who played for under 30 minutes). This third code also allowed for more nuanced coding—rather than forcing all students to fit under WS or P, thus risking miscategorization, the NA code could be used instead. Using this tri-code schema, inter-rater reliability analysis yielded a Cohen's κ [37] of .78, indicating acceptable agreement between raters was achieved.

2.4.3 Modeling Early Detection of Wheel-spinning

The final predictive model merged the initial feature engineering of event-stream features with the behavioral codes generated in the analysis above. To support early intervention for in-system personalization as well as teacher interventions, the final model was built to predict wheel-spinning (WS) at the end of week 12 (the last week of the study) using predictors from week 4 data. (Week 4 predictors were selected after subsequent weeks 5 and 6 were tested for model performance, but resulted in only marginal improvement.) Since each classroom was assigned exactly 12 weeks of play relative to start date, weeks as a time marker helped consistently align student progress across classrooms in relationship to the study design. It also allowed for implementation-focused behavior detection for the highest utility to teachers. With earlier detection of students getting stuck in the system, intervention can have greater impact on student progress in building core math skills.

Ultimately, the log file features (Table 1) were used as predictors in the model, while the behavior of wheel-spinning became the predicted variable. Using this full feature list, the WS detector was then built at the student level using RStudio, using the RWeka

package for data mining [38]. An appropriate set of algorithms were selected based on the categorical dependent variable, informed by related behavior modeling research in education (e.g. [39, 40]), including J48, CART, Random Forest, and Naïve Bayes. Models were evaluated using ten-fold cross validation, with a final selection based on the goodness metric of AUC ROC.

To achieve higher accuracy in correctly detecting and classifying the target class of students, the wheel-spinning students, we used rebalanced classes for all three methods tested. This approach is in alignment with similar detector-based analyses in digital learning contexts (e.g. [41, 42]). Specifically, the original classes P, WS and NA had a respective number of instances of 79, 39 and 14. We set the target number of instances for each rebalanced class to $n=100$. To obtain that number of observations per class, for a total of $n=300$, sampling with replacement was performed on each class. This resampling procedure was only performed on the training set for tree building purposes and all testing was performed on the original data distribution.

3. RESULTS AND DISCUSSION

3.1 Results

Ultimately, the CART algorithm produced the best model performance, achieving a cross-validated AUC of .676 in predicting wheel-spinning in week 12 with week 4 predictors, comparable to metrics in other game-based learning detector models (e.g. [39, 12]).

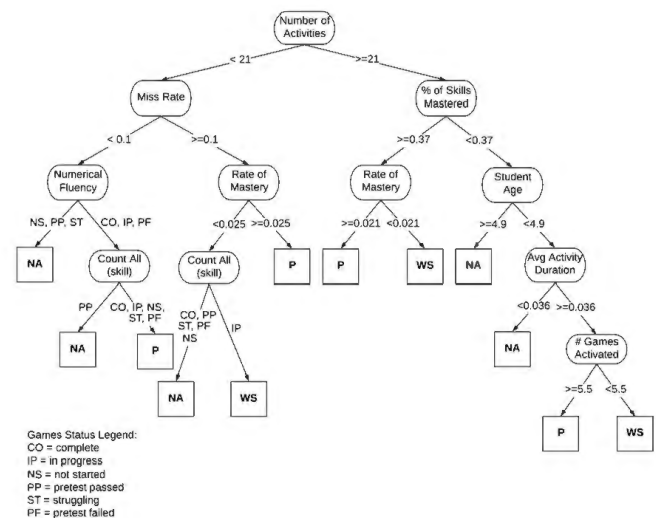

Figure 3. Final CART wheel-spinning predictor model.

Interestingly, in Figure 3 the first decision on the tree is the number of activities completed, with many students having less than 21 activities categorized as NA (insufficient information). Under this parent node, three core pathways emerge for wheel-spinners, covered from left to right on the tree: 1) low prior knowledge and low motor skill (via count all game, a low-level skill, and miss rate); 2) higher % of skills mastered but with very low efficiency (rate of mastery); and 3) younger students with low prior knowledge and very low efficiency in the system (with few games activated, higher time per activity and high number of activities per game). The first path suggests a group of students that may be in an earlier stage of development, both in terms of motor skill and prior knowledge (but not necessarily age). The second group, with the ability to master more skills with seemingly fewer motor skill issues, may represent students that

have more advanced development and prior knowledge but may need a bit more scaffolding and just-in-time support to learn the material. The last group may consist of younger students with low prior knowledge who need support more directly related to age-based maturity levels. These groups, implying differing levels of development and age, reflect clinical research which suggests wide variation in the relationship between age and developmental level in young children [43]. This suggests that developmental stage (rather than age alone) is a helpful differentiator in personalizing learning experiences for young students. To investigate implications of age and development for better learning design, these emergent groups suggest value in deeper exploration of student profiles in future work (discussed below). Overall, these model-derived groups offer insight into potential types of wheel-spinning that occur within the system, with the tree model allowing for early detection of unproductive persistence.

3.2 Discussion and Conclusion

Overall, the model of wheel-spinning yields insight into the important differentiation between unproductive and productive persistence, revealing multiple ways that student wheel-spinning manifests in data and enabling event-stream detection of this behavior in the event stream data. In turn, this real-time prediction can allow for very early intervention—both in-system and in classroom—for students displaying wheel-spinning behavior. For the system, this means it may be possible to offer more intelligent adaption to student needs, while for teachers (with limited time and resources) it may become possible to offer just-in-time information about which students most need help. This emergent behavior detection is especially important in games, which can have unexpected player pathways due to complex elements of narrative, agency, and failure-driven exploration—all of which converge to support the medium’s power of engagement in well-designed playful learning experiences.

Along this line of research in future work, there is an opportunity to generalize this detector to children using the game-based learning system outside of a study-specific context. The week-level data used in this study was centered around implementation, designed to flag to a teacher which students might be wheel-spinning after a certain amount of prescribed weekly dosage; however, converting this progress marker to an activity/elapsed time-based unit to build a model based on data in the wild can make this model applicable to an even broader base of learners. In addition, comparison between the classroom-based and broader event-stream based models may yield interesting insights. There is also an opportunity in this rich data stream (currently thousands of students) to hone the model for even higher AUC and predictive power. This includes iteration in feature engineering based on patterns that may arise in the larger data stream of students, using predictive modeling of wheel-spinning in a broader context of students (in formal and informal learning environments). Investigating player profiles based on detection results may also help determine groups of students struggling with the system based on motor skill, prior knowledge, and age/grade. Relatedly, better understanding how motor skill indicators in the data connected to more traditional measures of visual-motor skill (e.g. [44]) may also be valuable. Finally, dashboards highlighting detector-based insights to both parents and students for interpersonal support represent a key area for future work, with potential for student-level flagging for intervention, specific skills needing support (see Figure 2), recommendations for in-person

follow-up, and possible grouping of students in the same class for differentiated instruction.

Future work in expanding the scope of wheel-spinning research in the *MM* system can support the ability to generalize findings across broader age ranges and geographic areas, increasing the potential for impact on data-driven design, intelligent personalization, and interpersonal intervention. With information on behaviors like wheel-spinning and productive persistence, in combination with other evidence such as student prior knowledge, this work can inform designers about which instructional design in games needs revisiting, as well as providing adaptive logic and system overlays for just-in-time detection and intervention. Both in the system and beyond, this research can further the application of educational data mining to principled learning design, potentially expanding the field of intelligent game-based learning and supporting young learners in developing foundational academic skills at scale.

ABSTRACT

Knowledge tracing is the task of modeling each student's mastery of knowledge concepts (KCs) as (s)he engages with a sequence of learning activities. Each student's knowledge is modeled by estimating the performance of the student on the learning activities. It is an important research area for providing a personalized learning platform to students. In recent years, methods based on Recurrent Neural Networks (RNN) such as Deep Knowledge Tracing (DKT) and Dynamic Key-Value Memory Network (DKVMN) outperformed all the traditional methods because of their ability to capture a complex representation of human learning. However, these methods face the issue of not generalizing well while dealing with sparse data which is the case with real-world data as students interact with few KCs. In order to address this issue, we develop an approach that identifies the KCs from the student's past activities that are *relevant* to the given KC and predicts his/her mastery based on the relatively few KCs that it picked. Since predictions are made based on relatively few past activities, it handles the data sparsity problem better than the methods based on RNN. For identifying the relevance between the KCs, we propose a self-attention based approach, Self Attentive Knowledge Tracing (SAKT). Extensive experimentation on a variety of real-world dataset shows that our model outperforms the state-of-the-art models for knowledge tracing, improving AUC by 4.43% on average.

Knowledge Tracing, Massive Open Online Courses, Self-attention, sequential recommendation

1. INTRODUCTION

The availability of massive dataset of students' learning trajectories about their *knowledge concepts* (KCs), where a KC can be an exercise, a skill or a concept, has attracted data miners to develop tools for predicting students' performance and giving proper feedback [8]. For developing such person-

Figure 1: Left subfigure shows the sequence of exercises that the student attempts and the right subfigure shows the knowledge concepts to which each of the exercises belong.

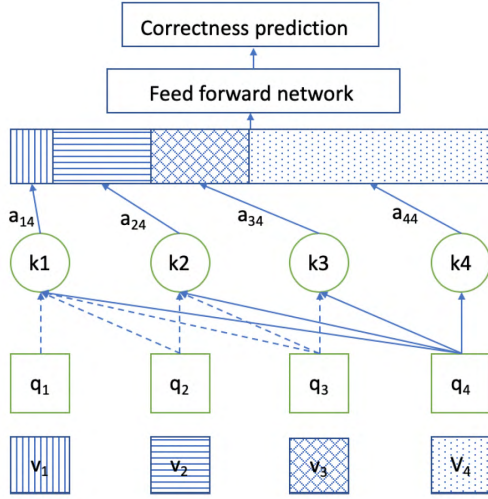

alized learning platforms, knowledge tracing (KT) is considered to be an important task and is defined as the task of tracing a student's *knowledge state*, which represents his/her mastery level of KCs, based on his/her past learning activities. The KT task can be formalized as a supervised sequence learning task - given student's past exercise interactions $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_t)$, predict some aspect of his/her next interaction \mathbf{x}_{t+1} . On the question-answering platform, the interactions are represented as $\mathbf{x}_t = (e_t, r_t)$, where e_t is the exercise that the student attempts at timestamp t and r_t is the correctness of the student's answer. KT aims to predict whether the student will be able to answer the next exercise correctly, i.e., predict $p(r_{t+1} = 1 | e_{t+1}, \mathbf{X})$.

Recently deep learning models such as Deep Knowledge Tracing (DKT) [6] and its variant [10] used Recurrent Neural Network (RNN) to model a student's knowledge state in one summarized hidden vector. Dynamic Key-value memory network (DKVMN) [11] exploited Memory Augmented Neural Network [7] for KT. Using two matrices, *key* and *value*, it learns the correlation between the exercises and the underlying KC and student's knowledge state, respectively. The DKT model faces the issue of its parameters being non-interpretable [4]. DKVMN is more interpretable than DKT as it explicitly maintains a KC representation matrix (*key*) and a knowledge state representation matrix (*value*). However, since all these deep learning models are based on RNNs, they face the issue of not generalizing while dealing with sparse data [3].

In this paper, we propose to use a purely attention mechanism based method, *transformer* [9]. In the KT task, the skills that a student builds while going through the sequence of learning activities, are related to each other and the performance on a particular exercise is dependent on his performance on the past exercises related to that exercise. For example, in figure 1, for a student to solve an exercise on "Quadratic equation" (exercise 5) which belongs to the knowl-

Shalini Pandey and George Karypis "A Self Attentive model for Knowledge Tracing" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 384 - 389

edge concept “Equations”, he needs to know how to find “square roots” (exercise 3) and “linear equations” (exercise 4). SAKT, proposed in this paper first identifies *relevant* KCs from the past interactions and then predicts student’s performance based on his/her performance on those KCs. For predicting student’s performance on an exercise, we used exercises as KCs. As we show later, SAKT assigns weights to the previously answered exercises, while predicting the performance of the student on a particular exercise. The proposed SAKT method significantly outperforms the state-of-the-art KT methods gaining a performance improvement of 4.43% on the AUC, on an average across all datasets. Furthermore, the main component (self-attention) of SAKT is suitable for parallelism; thus, making our model order of magnitude faster than RNN based models.

(a) Network of SAKT. At each timestamp the attention weights are estimated for each of the previous element only. Keys, Values and Queries are extracted from the embedding layer shown below. When j th element is query and i th element is key, attention weight is $a_{i,j}$.

(b) Embedding layer embeds the current exercise that the student is attempting and his past interactions. At every time stamp $t+1$, the current question e_{t+1} is embedded in the query space using Exercise embedding and elements of past interactions x_t is embedded in the key and value space using the Interaction embedding.

Figure 2: Diagram showing the architecture of SAKT.

2. PROPOSED METHOD

Our model predicts whether a student will be able to answer the next exercise e_{t+1} based on his previous interaction sequence $\mathbf{X} = x_1, x_2, \dots, x_t$. As shown in figure 2, we can transform the problem into a sequential modeling

Table 1: Notations

Notations	Description
N	total number of students
E	total number of exercises
\mathbf{X}	Interaction sequence of a student: (x_1, x_2, \dots, x_t)
x_i	i th exercise-answer pair of a student
n	maximum length of sequence
d	latent vector dimensionality
\mathbf{e}	Sequence of exercises solved by the student
\mathbf{M}	Interaction embedding matrix
\mathbf{P}	Positional embedding matrix
\mathbf{E}	Exercise lookup matrix
$\hat{\mathbf{M}}$	Past interactions embedding
$\hat{\mathbf{E}}$	Exercise embedding

problem. It is convenient to consider the model with inputs x_1, x_2, \dots, x_{t-1} and the exercise sequence with one position ahead, e_2, e_3, \dots, e_t and the output being the correctness of the response to exercises r_2, r_3, \dots, r_t . The interaction tuple $x_t = (e_t, r_t)$ is presented to the model as a number $y_t = e_t + r_t \times E$, where E is the total number of exercises. Thus, the total values that an element in the interaction sequence can take is $2E$, while elements in the exercise sequence can take E possible values.

We now describe the different layers of our architecture.

Embedding layer: We transform the obtained input sequence $\mathbf{y} = (y_1, y_2, \dots, y_t)$ into $s = (s_1, s_2, \dots, s_n)$, where n is the maximum length that the model can handle. Since the model can work with inputs of fixed length sequence, if the sequence length, t is less than n , we repetitively add a *padding* of question-answer pair to the left of the sequence. However, if t is greater than n , we partition the sequence into subsequences of length n . Specifically, when t is greater than n , y_t is partitioned into t/n subsequences each of length n . All these subsequences serve as input to the model.

We train an *Interaction embedding matrix*, $\mathbf{M} \in \mathbb{R}^{2E \times d}$, where d is the latent dimension. This matrix is used to obtain an embedding, \mathbf{M}_{s_i} for each element, s_i in the sequence. Similarly, we train exercise embedding matrix, $\mathbf{E} \in \mathbb{R}^{E \times d}$ such that each exercise in the set e_i is embedded in the e_i th row.

Position Encoding: Position Encoding is the layer in the self-attention neural network which is used for encoding the position so that like convolution network and recurrent neural network, we can encode the order of the sequence. This layer is particularly important in knowledge tracing problem because a student’s knowledge state evolves gradually and steadily with time. The knowledge state at a particular time instance should not show wavy transitions [10]. In order to incorporate this we use a parameter, position embedding, $\mathbf{P} \in \mathbb{R}^{n \times d}$ which is learned while training. The i th row of position embedding matrix, \mathbf{P}_i is then added to the interaction embedding vector of the i th element of the interaction sequence.

The output from the embedding layer is embedded interac-

tion input matrix, $\hat{\mathbf{M}}$ and embedded exercise matrix, $\hat{\mathbf{E}}$:

$$\hat{\mathbf{M}} = \begin{bmatrix} \mathbf{M}_{s_1} + \mathbf{P}_1 \\ \mathbf{M}_{s_2} + \mathbf{P}_2 \\ \dots \\ \mathbf{M}_{s_n} + \mathbf{P}_n \end{bmatrix}, \quad \hat{\mathbf{E}} = \begin{bmatrix} \mathbf{E}_{s_1} \\ \mathbf{E}_{s_2} \\ \dots \\ \mathbf{E}_{s_n} \end{bmatrix}. \quad (1)$$

Self-attention layer: In our model, we use the scaled dot-product attention mechanism [9]. This layer finds the relative weight corresponding to each of the previously solved exercise for predicting the correctness of the current exercise.

We obtain query and key-value pairs using the following equations:

$$\mathbf{Q} = \hat{\mathbf{E}}\mathbf{W}^Q, \mathbf{K} = \hat{\mathbf{M}}\mathbf{W}^K, \mathbf{V} = \hat{\mathbf{M}}\mathbf{W}^V, \quad (2)$$

where $\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V \in \mathbb{R}^{d \times d}$ are the query, key and value projection matrices, respectively, which linearly project the respective vectors to different space [9]. The relevance of each of the previous interactions with the current exercise is determined using the attention weights. For finding the attention weights we use the scaled dot product [9], defined as:

$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}}\right)\mathbf{V}. \quad (3)$$

Multiple heads: In order to jointly attend to information from different representative subspaces, we linearly project the queries, keys and values h times using different projection matrices.

$$\text{Multihead}(\hat{\mathbf{M}}, \hat{\mathbf{E}}) = \text{Concat}(\text{head}_1, \dots, \text{head}_h)\mathbf{W}^O, \quad (4)$$

where $\text{head}_i = \text{Attention}(\hat{\mathbf{E}}\mathbf{W}_i^Q, \hat{\mathbf{M}}\mathbf{W}_i^K, \hat{\mathbf{M}}\mathbf{W}_i^V)$ and $\mathbf{W}^O \in \mathbb{R}^{hd \times d}$.

Causality:

In our model, we should consider only first t interactions when predicting the result of the $(t+1)$ st exercise. Therefore, for a query \mathbf{Q}_i , the keys \mathbf{K}_j such that $j > i$ should not be considered. We use, causality layer to mask the weights learned from a future interaction key,

Feed Forward layer:

The self-attention layer described above results in weighted sum of values, \mathbf{V}_i of the previous interactions. However the rows of the matrix obtained from the multihead layer, $\mathbf{S} = \text{Multihead}(\hat{\mathbf{M}}, \hat{\mathbf{E}})$ is still a linear combination of the values, \mathbf{V}_i of the previous interactions. To incorporate non-linearity in the model and consider the interactions between different latent dimensions, we use a feed forward network.

$$\mathbf{F} = \text{FFN}(\mathbf{S}) = \text{ReLU}(\mathbf{S}\mathbf{W}^{(1)} + \mathbf{b}^{(1)})\mathbf{W}^{(2)} + \mathbf{b}^{(2)}, \quad (5)$$

where $\mathbf{W}^{(1)} \in \mathbb{R}^{d \times d}$, $\mathbf{W}^{(2)} \in \mathbb{R}^{d \times d}$, $\mathbf{b}^{(1)} \in \mathbb{R}^d$, $\mathbf{b}^{(2)} \in \mathbb{R}^d$ are parameters learned during training.

Residual Connections: The residual connection [2] are used to propagate the lower layer features to the higher layers. Hence, if low layer features are important for prediction, the residual connection will help in propagating them to the final layers where the predictions are performed. In the context of KT, students attempt exercises belonging to

a specific concept to strengthen that concept. Hence, residual connection can help propagating the embeddings of the recently solved exercises to the final layer making it easier for model to leverage the low layer information. A residual connection is applied after both self-attention and feed forward layer.

Layer normalization: In [1], it was shown that normalizing inputs across features can help in stabilizing and accelerating neural networks. We used layer normalization in our architecture for the same purpose. Layer normalization is also applied at both the self-attention and feed forward layer.

Prediction layer:

Finally, each row of the matrix \mathbf{F}_i obtained above is passed through the fully connected network with Sigmoid activation to predict the performance of the student.

$$p_i = \text{Sigmoid}(\mathbf{F}_i \mathbf{w} + \mathbf{b}), \quad (6)$$

where p_i is a scalar and represents the probability of student providing correct response to exercise e_i , \mathbf{F}_i is the i th row of \mathbf{F} and $\text{Sigmoid}(z) = 1/(1 + e^{-z})$

Network Training: The objective of training is to minimize the negative log likelihood of the observed sequence of student responses under the model. The parameters are learned by minimizing the cross entropy loss between p_t and r_t .

$$\mathcal{L} = -\sum_t (r_t \log(p_t) + (1 - r_t) \log(1 - p_t)) \quad (7)$$

3. EXPERIMENTAL SETTINGS

3.1 Datasets

To evaluate our model, we used four real-world datasets and one synthetic dataset.

- *Synthetic*¹: This dataset is obtained by simulating 4000 virtual students' answering trajectories. Each student answers the same sequence of 50 exercises, which are drawn from 5 virtual concepts with varying difficulty level.
- *ASSISTment 2009*² (*ASSIST2009*): This dataset is provided by ASSISTment online tutoring platform and is widely used for KT tasks. We conducted our experiments on the updated "skill-builder" dataset. The dataset is sparse as the density of this dataset is 0.06, shown in Table 2.
- *ASSISTment 2015*³ (*ASSIST2015*): ASSISTment 2015 contains students' responses on 100 skills. There are 19,917 students and 708,631 interactions. Although the number of records in this dataset is more than ASSISTment 2009, the average number of records per student is smaller because the number of students is larger. This dataset is the most sparse of all the available datasets, with a density of 0.05.

Table 2: Dataset Statistics

Datasets	#Users	#Skill tags	#Interactions	#Unique Interactions	Density
Synthetic-5	4000	50	200K	200K	1
ASSIST2009	4417	124	328K	35K	0.06
ASSIST2015	19917	100	709K	102K	0.05
ASSIST-Chall	686	102	943K	57K	0.81
STATICS	333	1223	190K	129K	0.31

The columns corresponding to #Users, #Skill tags and #Interactions represent the number of students, total number of exercise tags and the number of records, respectively. The column Density represents the density of each dataset (i.e., $\text{Density} = \frac{\text{\#Unique Interactions}}{(\text{\#Users} \times \text{\#Skill tags})}$).

- *ASSISTment Challenge (ASSISTChall)*: This data is obtained from ASSISTment 2017 competition⁴. It is the richest dataset in terms of the number of interactions with 942,816 interactions, 686 students and 102 skills. This dataset is the most dense dataset of all the available datasets because its density is 0.81.
- *STATICS2011 (STATICS)*: This dataset contains the interaction from an engineering statics course with 189,927 interactions, 333 students and 1223 skill tags. We adopted the processed data from [11]. It is also a dense dataset with a density of 0.31.

The complete statistical information for all the datasets can be found in Table 2.

3.2 Evaluation Methodology

Metrics: The prediction task is considered in a binary classification setting i.e., answering an exercise correctly or not. Hence, we compare the performance using the Area Under Curve (AUC) metric.

Approaches: We compare our model against the state-of-the-art KT methods, DKT [6], DKT+ [10], and DKVMN [11]. These methods are described in the introduction.

Model Training and parameter selection: We trained the model with 80% of the dataset and test it on the remaining. For all the methods, we tried the hidden state dimension $d = \{50, 100, 150, 200\}$. For the competing approaches, we used the same hyperparameters as reported in their respective papers. For initialization of weights and optimization, we used a similar procedure as [10]. We implemented SAKT with *Tensorflow* and used ADAM [5] optimizer with learning rate of 0.001. We used a batch size of 256 for the ASSISTChall dataset and 128 for the others. For datasets with a larger number of records, e.g., ASSISTChall and ASSIST2015, we used a dropout rate of 0.2, while for the remaining datasets, we used a dropout rate of 0.2. We set the maximum length of the sequence, n as roughly proportional to the average exercise tags per student. For ASSISTChall and STATICS dataset we use $n = 500$, for the ASSIST2009 $n = 100$ and 50, for the synthetic and ASSIST2015 datasets n is set to 50.

² The reported results are obtained by the best hyperparameter selection for each dataset individually.

4. RESULTS AND DISCUSSION

Student Performance Prediction: Table 3 shows the performance comparison of SAKT with the current state-of-the-art methods. On the Synthetic dataset, SAKT performs better than the competing approaches, achieving an AUC of 0.832 compared to 0.824 by DKT+. Even though Synthetic is the most dense dataset, SAKT outperforms RNN based methods because of the methodology used for generating Synthetic. For this dataset, each individual exercise is derived from only one concept. The probability of a student answering an exercise from this dataset correctly is determined using Item Response Theory [8] as, $p(\text{correct}|\alpha, \beta) = c + \frac{1-c}{1+\exp(\beta-\alpha)}$, where c denotes the probability of guessing it correctly, α and β are randomly chosen numbers to indicate the concept ability and exercise difficulty, respectively. Thus, in this dataset, the exercises belonging to the same concept are strongly correlated. SAKT, unlike other benchmarks, directly attempts to identify exercises belonging to the same concept and hence performs better than other methods. On ASSIST2009, SAKT performs better than competing approaches, gaining a performance improvement of 3.16% over the second best performing method. For ASSIST2015 dataset, SAKT shows an impressive improvement of 15.87%. We attribute this gain to the fact that attention mechanism leveraged by SAKT can learn and generalize well even when the dataset is sparse, which is the case with ASSIST2015 as its density is the least among the other datasets. For STATICS2011, our method achieves a performance improvement of 2.16% compared to DKT+. For ASSISTChall, our method performs at par with DKT. This can be attributed to the fact that ASSISTChall is the most dense dataset of all the real-world datasets.

Attention weights visualization: Visualizing the attention weights between the elements of past interactions (which serve as keys) and the exercise that the student is going to solve next (which serves as query) can help in understanding which exercises in the past interactions are relevant to the query exercise. With this motivation, we compute the sum of attention weights of each exercise pair ($e1, e2$) across all the sequences where $e1$ serves as query and interaction with exercise $e2$ serves as key. We then normalize the attention weights so that the sum of the weights for each query is one. This results in a *relevance* matrix in which each element, ($e1, e2$) represents the influence of $e2$ on $e1$. We perform our analysis on Synthetic because this dataset was generated with known hidden concepts and hence the ground

Table 4: Example of attention weights for some sequences in ASSIST2009 dataset.

Exercise tag	Past Interactions
Scale Factor	(Probability of Two Distinct Events,1): 0.000001, (Circle Graph, 1): 0.0001, (Circle Graph,1):0.001, (Division Fractions, 0): 0.99
Ordering integers	(Intercepts,0): 0.21, (Ordering positive decimals,1): 0.611 , (Multiplication whole numbers,1): 0.09, (Proportion,1):0.033
Rate	(Interior Angles Figures, 0):0.005, (Algebraic Simplification,0) : 0.009, (Rate,0):0.5 , (Interior Angles Figures, 0):0.1, (Algebraic Simplification,0) : 0.12

The columns corresponding to Exercise tag refers to the query (i.e., the exercise for which we have to predict the student's performance) and Past Interactions refers to the sequence of interactions that has been observed for that student, respectively. **red** colored elements in the right column represent the most important element among the past interaction elements

(a) Heatmap depicting the attention weights between each pair of exercises. Note that, the weight assigned for pair (i, j) , where $j > i$ is always zero because all the sequences consists of exercises in the same order from

(b) Graph depicting the relevance between exercises. The relevance is determined by the attention weights learned between the exercises using SAKT. We observe a perfect clustering of latent concepts.

Figure 3: Visualizing attention weight of Synthetic dataset.

truth regarding the relevance of different exercises are known to us. Figure 3a shows the heatmap corresponding to the *relevance* matrix of exercises in Synthetic. For Synthetic, all the sequences consist of all exercise tags in the same sequence starting from 1 to 50.

In order to build the influence graph between the exercise tags, as shown in Figure 3b, we use the *relevance* matrix. Firstly, we draw out the first exercise in the sequence that belongs to each hidden concept, and visit each row of the *relevance* matrix, and connect the exercise corresponding to that row to the first two exercises ranked based on edge weight, which is proportional to the attention weights between the pair of exercises. We can see that the based on the attention weights, we are able to achieve the perfect clustering of the exercise tags based on the hidden concepts from which they are derived. An interesting observation is that two exercises which occur far apart in the sequence but belonging to the same concept can be identified by SAKT. For example, as shown Figure 3b a query on exercise 22 assigned most weight to the key with exercise 5 even when they occur far apart in the sequence.

Two exercises which are relevant to each other tend to have high attention weights as the performance on one of them impacts the performance on the other. Additionally, in the real-world scenario, the exercises which occur close in the sequence tend to belong to the same concept. Thus, we expect that the attention weights biased towards the exercises that occur recently in the interaction sequence. To illustrate this, we manually analyzed ASSIST2009 dataset to visualize the attention weights for some selected samples. Table 4 shows some of the exercises along with the past interactions and attention weights assigned to each interaction.

Ablation Study: Table 4 shows the performance of default SAKT architecture and all the variants on all the datasets (with $d = 200$).

No Positional Encoding (PE): In this variant of the default architecture, we removed the positional encoding. As a result, the attention weights assigned for predicting the performance of student on a particular exercise depends only on the interaction embedding, without being affected by its position in the sequence. In case of ASSIST2009 and ASSIST2015, the dataset is sparse and hence the impact of removal of PE is not much pronounced as is the case with the dense dataset such as ASSISTChall and STATICS.

No Residual Connection (RC): RCs shows the importance of low level features i.e., the interaction embedding while making the prediction. Since our architecture is not very deep, the RC do not contribute much to the performance of the model. In fact removal of residual connection gives better

Table 5: Ablation Study

Architecture	Synthetic	ASSIST 2009	ASSIST 2015	ASSIST Chall	STATICS
Default	0.832	0.848	0.854	0.734	0.853
No PE	0.827	0.842	0.849	0.715	0.832
No RC	0.823	0.847	0.857	0.709	0.834
No Dropout	0.832	0.845	0.851	0.711	0.840
Single head	0.823	0.828	0.845	0.709	0.851
0 block	0.826	0.837	0.822	0.634	0.819
2 blocks	0.827	0.840	0.853	0.724	0.845

performance than default for the ASSIST2015 dataset.

No Dropout: Dropout is used in neural network to regularize the model so that it can generalize better. Overfitting of the model is more effective for dataset with less number of records compared to the number of parameters of model. As a result, role of dropout is more effective for ASSIST2009 dataset and STATICS dataset.

Single head: Instead of using 5 heads as is the case in default architecture, we tried a variant of using only one head. Multiple heads help in capturing the attention weights in different subspaces. Using single head consistently drops the performance of SAKT on all the datasets.

No block: When no self-attention block is used the prediction of the next exercise depends only on the last interaction. It can be seen that without attention block the performance is significantly worse than that of default architecture.

2 Blocks: Increasing the number of blocks of self-attention increases the number of parameters of the model. However, in our case this increase of parameters does not prove to be useful in improving the performance. The reason being an important aspect of prediction of performance of student at an exercise is dependent on his performance on the past relevant exercises. Adding another block of self-attention makes the model more complex.

Training efficiency: Figure 4 demonstrates the efficiency of various methods based on their run times on GPU during the training phase. Comparing the computational efficiency, SAKT only spends 1.4 seconds in one epoch which is 46.42 less than the time taken by DKT+ (65 seconds/epoch), 32 times less than DKT (45 seconds/epoch) and 17.33 times less than DKVMN (26 seconds/epoch). We conducted the experiments on a single GPU of type NVIDIA Titan V.

Figure 4: Training Efficiency on ASSIST2009 dataset.

5. CONCLUSION AND FUTURE WORK

In this work, we proposed a self-attention based knowledge tracing model, SAKT. It models a student's interaction history (without using any RNN) and predicts his performance on the next exercise by considering the relevant exercises from his past interactions. Extensive experimentation on a variety of real-world datasets shows that our model can outperform the state-of-the-art methods and is an order of magnitude faster than the RNN-based approaches.

Success prediction in MOOCs

A case study

Antoine Pigeau, Olivier Aubert and Yannick Prié

firstName.lastName@univ-nantes.fr

ABSTRACT

Success prediction in Massive Open Online Courses (MOOCs) is now tackled in numerous works, but still needs new case studies to compare the solutions proposed. We study here a specific dataset from a French MOOC provided by the OpenClassrooms company, featuring 12 courses. We exploit various features present in the literature and test several classification models.

1. INTRODUCTION

Multiple models and data mining methods for learner success prediction in a Massive Open Online Courses (MOOCs) are proposed by many works in the literature [1], with different conclusions about which model provides the best performance. The quality of the results seems to highly depend on the input dataset, and on the selected or computed features. Generalization of the methodology for success prediction seems now ongoing [1], but we still need new case studies to improve the accuracy and insights obtained by these methods.

This work presents a case study on a new dataset, provided by OpenClassrooms, a major online courses french company. We test several models using classification algorithms and sequence-based approaches, such as process and pattern mining. Our study aims at enriching previous results obtained for different datasets published in the literature.

Our first contribution in this work is the comparison of 8 classification models. Random Forest, AdaBoost, Support Vector Machine (SVM), logistic regression and neural networks are first applied, followed by sequence-based approaches: an LSTM neural network, a process mining method and a proposal of a solution based on a sequence mining method. The second contribution consists in experimental results obtained from a new dataset for a success prediction task. While most papers only focus on 1-5 courses [1], we use here 12 different courses from the same platform.

Antoine Pigeau, Olivier Aubert and Yannick Prié "Success prediction in MOOCs - A case study" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 390 - 395

The remainder of this paper is organized as follows: section 2 surveys previous work related to success prediction. Section 3 presents the dataset used for the experiments with details on the raw data used to compute features. Section 4 describes features obtained from the literature and their adaptation to our context. Section 5 presents the classification methods that we applied. The result of our experiments are detailed and discussed in section 6. We conclude by summarizing our work and drawing perspectives in section 7.

2. RELATED WORK

Prediction of dropout or success in MOOCs is carried out in numerous works [1]. The goal is to improve the performance of the learners by detecting a possible failure in advance. Such a detection could for instance lead to a teacher intervention to increase the learner engagement in the course.

The input data for such a prediction is based either on assignments [2, 3, 4, 5, 6] or clickstreams [7, 8, 9, 10]. Social activities can also be included to assess the learner engagement in a course [2, 3, 5].

Classification methods rely on common approaches such as linear regression, logistic regression, K-nearest neighbors, random forests, decision trees, support vector machines, hidden Markov models and neural networks. Because the course context is different for each study, it is hard to determine which model will be the best for a prediction task. Support vector machine is the best method obtained for [5] while random forest performs better in [6]. The conclusion of [2] states that prediction performance depends more on the features computed than on the model.

Several temporal data mining methods are proposed in the literature [1, 8, 9]. Recurrent neural networks are assessed for dropout detection and experiments conclude that LSTM recurrent networks present the second best results in [11] (where a Nonlinear State Space Model is slightly better). [9] proposes a solution based on process mining to emphasize a correlation between the way learners browse the course and their performances. Other approaches use sequence mining algorithms to predict learner skills [8].

In the present work, we test some of the common shallow methods proposed in the literature, as well as neural network approaches. We also explore a solution based on process mining, and propose one based on sequence mining. For all

Table 1: Number of learners per group for each course of the OpenClassrooms dataset, after cleanup. The first column presents the total number of learners and the two last ones detail the number of passing and failing learners.

these algorithms, we assess a large set of features adapted from the literature.

3. INPUT DATA

OpenClassrooms is a MOOC platform that provides courses in various domains, from art and culture to computer science. All courses are freely accessible anytime, and paid services are proposed for supplementary features such as online help and certificates of achievement. Courses are generally composed of texts, videos or e-books that users can browse, read or download after a registration process. Based on the properties proposed in [1], these courses can be characterized as follows:

- massive, open and online: thousands of learners can follow the courses freely. Paid access is provided to get an access to a tutor or a completion certificate;
- no-stakes: the learner can complete a course without certification or credit;
- asynchronous: learners are free to register, browse the content, or complete a course. There is no constraint on dates for enrollment or assignments. This point is important and has an impact on the choice of features used as input for the prediction model;
- heterogeneous: learners have various motivations and mostly come from francophone countries since courses are in french.

In this study, we are considering a dataset covering 12 courses in the domains of programming languages, project management and startup creation. The two leftmost columns of table 1 present for each course its name and the total number of learners that followed it, from 2014 to 2016.

The provided courses are composed of static web pages and quizzes/assignments, and do not contain any video. A course is composed of chapters, divided in sections, and of exercises based on quizzes and assignments. To succeed in a course, a learner must obtain an average grade on all exercises higher than 70/100 (the exercises are quizzes automatically graded).

The input format of learner activity is a clickstream dataset. Each access to a resource is recorded as one event in a log file. The granularity of the retrieved events varies among different courses. Apart from Audace Entreprendre, Node JS, XML and Java (in bold in table 1), which are traced at the section level, all courses present a chapter granularity.

The first step applied on the raw dataset consists in segmenting the learners' sequences of events into sessions. This session detection step aims to enrich some features related to the learners' regularity, the duration, or the number of events in the working sessions. The learners' sessions are determined from the raw sequences with the method proposed in [12], where a session is defined as *a delimited and sustained set of pages visited by the same user within the duration of one particular visit to a particular website*. Once sessions are determined, a cleaning task is performed: learners with only one session and no exercise attempt are removed. We associate this behaviour to learners that want to check the content of the course and do not really intend to follow it.

Discussion with the OpenClassrooms company about their needs lead us to define two groups for our goal of success prediction:

- passing group: set of learners that obtained an average grade equal to or higher than 70/100 for a course;
- failing group: set of learners that did not obtain an average grade higher than 70/100. This group contains all the learners that either quit the course or completed all exercises but failed to obtain a grade higher than the 70/100 validation threshold.

Our choice for the terms "Pass / Fail" is based on [1], where it is defined that *A student typically passes a course if they meet or exceed an instructor-specified overall grade threshold; otherwise they fail*.

The two rightmost columns of table 1 present the number of learners in each group for the 12 courses of the dataset, after the cleaning step. As commonly encountered in MOOC contexts, these groups are clearly unbalanced: on average, the passing group represents 15% of the learners. Courses of table 1 are ordered according to the percentage of passing learners.

4. FEATURES

Table 2 presents our candidate features set. This set regroups an adaptation of the best features identified in [2, 7, 13, 14, 15]. We needed to adapt some of the features due to differing contexts for our MOOC. A set of regularity features proposed in [10] was also used in our experiments: the features PDH, PWD, WS1, WS2, WS3, FDH, FWH and FWD were tested for our classification task. Check [10] for more details on these features.

Several options are possible to generate features depending on the considered machine learning approach:

- basic features: features are computed for the whole considered period (after x weeks of the course for instance). These features do not evolve with time;
- temporal features: features are computed for succes-

Category	name	description	abbrev.
Activity	total duration	total time spent on the course	totalDuration
	window duration	time spent from the first event to the last one	windowDuration
	linearity	ratio between the number of correct transitions, w.r.t. the structure of the course and the number of transitions in the sequence	linearityRatio
	# events per resource	# of accesses per resource	#eventPerR
	duration per resource	total time spent on each resource	durationPerR
	average duration per resource	avg duration spent on each resource	avgDurationPerR
	average session duration	avg duration of user sessions	avgSessionDuration
	average # events in session	avg number of events in each user session	avg#eventSession
Inter-activity periods	median of intertime	median of the time spent between sessions	medianInterTime
	duration before assessment*	time spent before each assessment	durationBeforeA
	# events before assessment*	# of events before each assessment	#eventBeforeA
	# sessions before assessment*	# of sessions between each assessment	#sessionBeforeA
	# events per day before assessment*	average number of events per day between each assessment	#eventPerDayBeforeA
	# sessions per day before assessment*	avg # of sessions per day between each assessment	#sessionPerDayBeforeA
	time since last event*	time without activity after 1, 2,..., n weeks (n=7 weeks in our experiment)	timeSinceLastEvent
Assignment	marks*	all marks obtained for each quiz	marks

Table 2: Features used for our experiments: this set is composed of features identified in our literature review, adapted to the characteristics of our dataset (* indicates the features defined by a set of values).

sive time periods in order to emphasize their evolution all along the course. The period commonly used in the literature seems to be one week [1];

- temporal features with stacking: similar to the previous method but each feature of a period is stacked with the previous one. Practically, it consists in adding the values of week n with those of week $n+1$.

5. PREDICTION TASK

In this section, we present different classification methods tested for our prediction task of passing/failing. We start with the baseline methods commonly applied for this kind of task and then detail a process mining approach and our proposal based on a sequence mining solution.

5.1 Baseline approaches

In order to compare our results with other available works in the literature, we experimented with the following methods: Random Forest, AdaBoost, SVM, logistic regression, dense neural network and LSTM neural network.

A first step of feature selection is necessary for logistic regression and SVM models. We rely here on a wrapper method with a forward selection to emphasize the best features. A subset of features is iteratively built, starting from an empty set and adding one by one the features that best improve our model's accuracy for the whole set of courses. The process is stopped when accuracy does not increase anymore.

Except for LSTM neural network that directly relies on a sequence of features, other methods can deal with several

types of input features: basic features, temporal features and temporal features with stacking. We test each possibility in our experiment, to determine in what measure this choice impacts the performance of the prediction.

5.2 Process mining approach

Process mining was initially a method to analyze business processes for process discovery, process conformance checking and process improvement. In the context of online courses, this method proposes to study the behavior of learners during a course, by emphasizing common paths in course resource navigation.

The classifier for our prediction task is built from the outputs of process discovery and conformance checking methods. Our process discovery relies on the Heuristic Miner algorithm [16]. This algorithm is robust, and deals with the majority of common problems in process detection. Models for failing and passing are built with this algorithm for each course. Our conformance checking solution relies on an algorithm based on an alignment method [16]. Our prediction task is carried out by computing the fitness of a learner on both failing and passing models, and affecting him to the group with the best fitness.

The input dataset of a process mining algorithm is a set of traces, where each trace represents the sequence of activities of one learner. In our context, an activity is an access to a resource and is defined with the id of this resource. Because the grades and the duration of each access are lost, a categorization step is carried out on each event of a learner's trace. It consists in updating the resource ids (the activity) as follows: for an exercise id, the new id depends on success or failure. For a chapter/section, the new id depends

Sequence length	Random forest	AdaBoost	SVM	Logistic regression
25%	marks, durationPerR, #sessionPerDayBeforeA, #eventBeforeA, avgDurationPerR	marks, avg#eventSession, durationPerR, avgDurationPerR	marks, #eventPerR, #sessionPerDayBeforeA, durationBeforeA	#eventPerR, marks, durationBeforeA, #sessionBeforeA, #eventPerDayBeforeA
50%	marks, #sessionPerDayBeforeA, #eventPerDayBeforeA	marks, avgDurationPerR, durationPerR, #eventPerR	#eventPerR, marks, #eventBeforeA, #eventPerDayBeforeA	#sessionBeforeA, #eventPerR, marks, #eventBeforeA
75%	marks, #sessionPerDayBeforeA, #eventPerDayBeforeA	marks, avgDurationPerR, durationPerR	marks, #eventPerDayBeforeA, #eventPerR, #sessionBeforeA	marks, #eventPerR
100%	marks	marks	marks	marks

Table 3: Best features for the different sequence lengths for random forest, AdaBoost, SVM and logistic regression models. This result is an aggregation of the best features obtained on each course separately. For each model and sequence length, features are ordered from most to least pertinent.

on the duration spent on the resource, using 3 classes of short/medium/long durations.

5.3 Sequence mining approach

With this approach, our goal is to determine whether different groups of learners present distinct frequent sub-sequences of events in their traces.

Our first step is to build the passing model (by retrieving the frequent sequence on only the passing learners) and the failing model. We rely on the VMSP algorithm to generate the maximal frequent sequences on both groups. Note that all sub-sequences of a maximal sequence are also frequent sequences, thus we still obtain all the frequent sequences.

Our second step is to compute a similarity score between a model and a learner's sequence. Our proposal consists in tessellating the new learner sequence with the larger frequent sub-sequences of the models. Practically, we try to map each frequent sequence on the learner sequence. The mapping obtained is used to compute a similarity score:

1. for a frequent sequence of length n in the model, generate all k -grams with k between 2 and n ;
2. map all k -grams one by one on the learner sequence, keeping the mapping with the larger k -gram;
3. repeat the steps 1-2 for all frequent sequences;
4. for each item position of the learner sequence, a score is computed as the length of the longer k -gram that maps this position. The similarity score is then obtained by summing up all these positions' scores.

The input dataset for this method is similar to the one used for our process mining approach. Each learner's event is categorized with our previous method (see section 5.2).

6. EXPERIMENTS

For all the following experiments, a cross validation 80% train - 20% test is carried out 10 times on each course separately. For the neural network approaches, the training set is divided into a train set, a validation set and a test set. Input features are standardized. The computation of temporal features is carried out by grouping the sessions into 7 days

periods. For each period, all features, except the regularity ones, are computed.

Neural networks present the advantage of avoiding the laborious feature selection step, but still need some tuning for determining a correct architecture with its optimization parameters. Our first task was to assess several candidate architectures, varying the number of layers and units. Our prediction tasks were carried out on all courses and results were aggregated. The best accuracies were obtained with the following parameters: [Dense Layer of 512 units, Dropout layer, Dense Layer of 256 units, Dropout layer, Dense layer of 1 unit with a sigmoid activation].

A similar search was carried out for the architecture of the LSTM solution, leading to the following parameters: [LSTM layer of 32 units, Dense layer of 1 units with a sigmoid activation]. The input of the LSTM algorithm, a time series, was computed as follows: each session is considered as a time step. For a specific learner, the input features for time t is computed with the learner t^{th} session and each element of a learner's time step is stacked with its previous element (a padding is applied to provide the same time's series length for each learner).

Finally, in order to assess our prediction at different time steps of the learning process, classification tasks are tested on truncated versions of the sequences. Experiments provide results for 25%, 50%, 75% and 100% of learner's sequence length (number of events).

In the following, the best features for random forest, logistic regression, SVM and AdaBoost models are first presented. Second, the results of the prediction task are detailed for each model.

6.1 Best features selection

The best features obtained for the shallow methods are presented in table 3. The best features for SVM and logistic regression are obtained with the wrapper method described in section 5.1. Best features on each course were computed with a 10 times 80%-20% cross validation, leading to a score for each feature depending on its ranking. These scores were

		25%			50%			75%			100%		
		A.	P.	F.	A.	P.	F.	A.	P.	F.	A.	P.	F.

	Dense NN	88%	36%	92%	83%	18%	88%	79%	17%	82%	78%	18%	83%

Table 4: Accuracies of the different models tested. A., P. and F. stand respectively for All, Pass and Fail

then aggregated among the courses. For random forest and AdaBoost, the weights provided by the learning algorithms have been used. For each method and sequence length, we selected the features with the best scores until a sudden drop appeared (the elbow method).

Clearly, the number of best features decreases with the increase of the sequence length available for the classification task, leading to the sole use of marks (feature marks) for full length. The marks feature is obviously pertinent for all sequence lengths.

If we ignore marks, random forest, logistic regression and SVM seem more related to inter-activity periods features while AdaBoost is associated to activity features. The best features concern mainly the marks, the activity intensity and the activity intensity between assessments. No regularity feature appears in the best features list for any model.

In the following, the aggregated best features obtained for SVM and logistic regression models are used to provide the results of our prediction task.

6.2 Best models

Table 4 presents the aggregated accuracies obtained for each model on each course separately, with basic features, temporal features and temporal features with stacking.

Each row is associated to a model and the columns present the sequence length used to fit the model (25%, 50%, 75% and 100%). The sub-columns (A., P., F.) stand for All, Pass and Fail, respectively for the overall accuracy, the accuracy for the passing learners and the accuracy for the failing learners.

Among the shallow classification methods, the Adaboost and logistic regression models present the more balanced results on both the passing and failing groups: Adaboost

seems more reliable to detect the failing learners while the logistic regression model performs better on the passing group. The Random Forest solution provides good results on balanced courses but clearly fails on very unbalanced ones (see the 28% accuracy on the passing group). The SVM model presents results similar to the logistic regression model, except for the passing learner accuracies which are clearly lower.

Compared to the best shallow models, the dense neural network presents a poor performance on passing learners and does not significantly outperform failing learner prediction. In our opinion, the lack of passing learners for each course in the train set does not enable to fit appropriately the parameter of the network. The LSTM model provides a result similar to the dense neural network, but with a higher computation cost. Hence we do not recommend these neural-based models in our context.

The process mining model presents very low scores. Our explanation is that the graphs generated by the heuristic miner algorithm on the two learner groups (passing and failing) contain the same navigation paths. Traces for passing or failing learners can then be replayed on both graphs with a good fitness.

A similarly bad result is also obtained with the sequence mining model. It can be explained by the fact that frequent sequences of failing learners are short and almost all included in the frequent sequences of the passing learners. Passing frequent patterns are more numerous and longer (longer patterns involve an increase of the similarity score between a model and an input learner trace). It is then more likely to find a better similarity between a learner sequence and the passing learner model. Our conclusion for the process and sequence mining approaches is that passing and failing learners do not present a discriminant behavior on the way they browse the courses.

The second and third parts of table 4 present the average accuracies when temporal features are used for the input dataset of the models, without and with stacking. Compared to the results obtained with the basic features, the results with the temporal features with and without stacking are lower for all models on all sequence lengths, with a clear drop on the accuracies of the passing learners. To conclude, the temporal features do not provide any improvement in our experiments.

To summarize, our experiments show that shallow models present the best results for our dataset. Among them, AdaBoost and logistic regression present the best results respectively for the failing group and the passing group. Another observation is that contrary to several experimental results [8, 9], our temporal data mining approaches (temporal features, LSTM, process mining and sequence mining solutions) do not perform well on our data set. Our conclusion here is that no difference can be found in the way learners access the course resources.

7. CONCLUSION

The objective of our work was to assess several solutions for predicting success in the context of Massive Online Open Courses, using a new dataset provided by the OpenClassrooms company, a major online course enterprise in France.

From our experimental results, we reached the following conclusions:

- failing and passing learners do not seem to present differences in the way they browse a course. Neither specific paths nor specific patterns are identified with our proposed solutions to discriminate between passing and failing learners;
- best features depend on the model used for the prediction tasks;
- temporal features do not increase the performance of the prediction task;
- the best models to detect failing and passing learners are respectively based on AdaBoost and logistic regression solutions.

A short term perspective work is to apply the same prediction tasks on other MOOC datasets, in order to validate our previous conclusions in other learning environments.

ABSTRACT

Course selection is a crucial and challenging problem that students have to face while navigating through an undergraduate degree program. The decisions they make shape their future in ways that they cannot conceive in advance. Available departmental sample degree plans are not personalized for each student, and personal discussion time with an academic advisor is usually limited. Data-driven methods supporting decision making have gained importance to empower student choices and scale advice to large cohorts. We propose *Scholars Walk*, a random-walk-based approach that captures the sequential relationships between the different courses. Based on the “wisdom of the crowd” and the students’ prior courses, we recommend a short list of courses for next semester. Our experimental evaluation illustrates that Scholars Walk outperforms other collaborative filtering and popularity-based approaches. At the same time, our framework is very efficient, easily interpretable, while also being able to take into consideration important aspects of the educational domain.

Keywords

course recommendation, Markov chains, random walks, sequential recommendation, higher education

1. INTRODUCTION

The general purpose of higher education is to offer programs, which will help learners to gain knowledge throughout their studies. Students enjoy a plethora of offerings. However, course selection can be “messy and unorganized” [3] as it depends on many factors that students need to consider. Students have to balance personal preferences (interests, objectives, and career goals) and general education and degree program requirements. As a result, course selection can be a non-trivial task.

Decisions can be made based on manual guides offered from each department, but these are not tailored to individual

cases [7] in a higher education setting. Personalized assistance can be given by academic advisers, however this is not scalable with large cohorts with thousands of students. The ratio of student to advisor may be very high [14], limiting the adviser-advisee discussion time. Additionally, college students take on average up to 20% more courses than required [2]. Better advising can help alleviate these problems. We need predictive models that can be employed to enable strategic action and attain better results. In this paper, we focus on appropriately designing a course recommendation system (CRS) that could facilitate the conversation between advisors and students for future planning.

There are several existing approaches to generate a set of courses to recommend for next semester. Their majority suggest courses based on either the constraints and requirements that they satisfy or their expected grades. This paper introduces *Scholars Walk*, a random-walk based approach for the course selection problem. It describes a personalized model that takes advantage of the sequential nature of course selection. We assume that students’ choices for the next term depend on the courses they have taken so far. In our approach, we build a Markov chain for each degree program over the courses taken consecutively. Then, we perform a random walk, starting from the courses that students took in the previous semester. We evaluated the proposed approach on a number of different departments with different subjects and characteristics. Scholars Walk overall outperforms other competing approaches in all the metrics considered in this paper.

2. RELATED WORK

Recommender systems have been broadly applied within the context of student learning [16]. We will further review the different approaches developed to help students select a subset of courses to register for an upcoming semester. The first course recommender systems are based on constraint satisfaction [22]. The sequence-based recommender [24] also considers complex constraints to improve the expected time-to-degree and GPA. A related body of work involves mining of association rules. Al-Badarenah et al. [1] cluster the students based on their grades first. Nguyen et al. [18] apply sequential rule mining in (course, grade) pairs and recommend the courses with the best performance. A different CSR was proposed by Esteban et al. [10], where there is available information about students’ satisfaction after taking a course.

n , m are the number of students and courses.

%pop is the course popularity (percentage of students that took a course at least once).

The last column (flex) is the degree flexibility.

Recently, recurrent neural networks (RNNs) have been successfully applied within the educational domain. Long Short Term Memory (LSTM) networks have been used for grading prediction [13, 20]. In terms of course recommendation, a combination of LSTMs and skip-gram models has also developed to balance implicit and explicit student preferences [23]. Morsy et al. [17] have also used RNN to recommend courses which are expected to help maintain or improve students' GPA. Other approaches include a Markov-based model [15], that represents the sequence of courses taken as a stochastic process. Garner et al. [11] build a co-enrollment network and extract features for a network-based structural model. Finally Elbadrawy et al. [9] propose using the academic features to improve the recommendation performance.

3. DOMAIN & DATASET

This work focuses on the undergraduate students in a traditional educational institution. We used a dataset from the University of Minnesota that spans more than 10 years. The A–F grading scale (A, A–, B+, B, B–, C+, C, C–, D+, D, F) is used. Courses in which a student receives less than a C– do not count toward satisfying degree requirements.

We extracted the degree programs that have at least 500 graduated students from 23 different majors. We only kept students that actually received their degree and had at least three consecutive semesters with valid courses. We selected the 40 most frequent courses and the courses that belonged to frequent subjects. A subject is considered frequent if stu-

dents have taken at least three courses that belong to that subject on average. We removed instances without an A–F grade, and non-academic courses, like independent/directed study or field study. We did not consider offerings in the summer semester. As these are less common, they would distort the course sequence of students not enrolled in summer. Basic statistics for each degree program are shown in Table 1. The average course popularity (%pop) for course i is the percentage of students that have taken i at least once during their studies. The degree flexibility (flex) is a measure of how different are the course selections that students make. It is one minus the average Jaccard similarity coefficient for every pair of students. The Jaccard similarity is computed as the number of courses that two students have in common divided by the minimum courses that student has taken them.

4. PROPOSED METHOD

4.1 Assumptions & Notation

In the context of course recommendation for higher education, we make the following assumptions:

1. Time is discrete and moves in steps, from one semester to the next.
2. There is a relative ordering of the courses in terms of course levels, difficulty or material covered.
3. Learning is seldom non-sequential; each course completed provides some knowledge and experience that can be used in future courses. As a consequence, sequence matters in course selection.
4. In the absence of enough domain experts, the order in which courses are taken by students historically can reveal useful information on the curriculum and degree requirements.
5. We know the number of courses that the student will take next semester.

For the rest of the paper we will adopt the following notation. When we use the word *target* we will refer to the student/course/semester for which we want to generate recommendation. Matrices are denoted with capital bold letters, while vectors are denoted with lower bold letters. Calligraphic letters will be used for sets.

The set of students is \mathcal{S} and has size m . The set of all courses is denoted by \mathcal{C} , $|\mathcal{C}| = n$. Student j has an enrollment history \mathcal{H}_j , that is an ordered set of courses, $\{\mathcal{C}_{j,1}, \dots, \mathcal{C}_{j,t}, \dots, \mathcal{C}_{j,t_j}\}$, where $\mathcal{C}_{j,t}$ is the set of courses taken in semester t and t_j is the last semester that the student took courses. Table 2 presents the symbols we used.

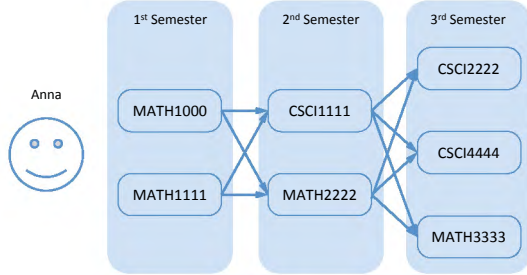

4.2 Building the Markov chain

Markov models satisfy the Markov property, i.e., the conditional probability distribution of future states depends only on the current state. In the simplest Markov model, known as first-order, each state is formed by a single action, i.e., a student took a course. In the case of K -th-order models, the state-space will correspond to all possible sequences of K actions. As the available data could not adequately support the number of states of higher-order chains, these models would suffer from reduced coverage and possibly worse overall performance [6]. Therefore, we adopted a first-order

Table 2: Notation.

n, m	number of courses, students
i, i'	indexes for courses
j, j'	indexes for students
t_j	number of semesters that j has taken courses
t	index for semesters
\mathcal{C}, \mathcal{S}	set of courses, courses
\mathcal{A}	set of states in Markov chain $\{\mathcal{A}_1, \dots, \mathcal{A}_n\}$
\mathcal{H}_j	enrollment history of student j
$\mathcal{C}_{j,t}$	course that student j took in semester t
\mathbf{T}, \mathbf{F}	matrices ($n \times n$)
$\mathbf{T}_{k,l}$	the (k, l) element of matrix \mathbf{T}
\mathbf{T}_k	the k -th row of matrix \mathbf{T} ($1 \times n$)
$\mathbf{T}_{:,l}$	the l -th column of matrix \mathbf{T} ($n \times 1$)
\mathbf{u}	personalization vector ($1 \times n$)
$\mathbf{p}^{(k)}$	state vector ($1 \times n$) at timestep k

Figure 1: Example: Anna’s enrollment history.

Markov chain. We assume that the next-semester courses depend only on the courses that the student is taking the current semester.

Markov models are represented by the parameters $(\mathcal{A}, \mathbf{T})$, where \mathcal{A} is the set of states for which the Markov model is defined; and \mathbf{T} is an $(n \times n)$ transition probability matrix (TPM), where n is the number of states (i.e., courses). In this context, state \mathcal{A}_i is associated with the fact that the student took the course i . Each entry $\mathbf{T}_{i,i'}$ corresponds to the probability of moving to state $\mathcal{A}_{i'}$ when the process is in state \mathcal{A}_i , i.e., taking course i' after course i . Note that this matrix is not symmetric, i.e., $\mathbf{T}_{i,i'} \neq \mathbf{T}_{i',i}$, as the order in which the courses are taken matters.

Based on the historical enrollment information of the students, we first compute \mathbf{F} , an $(n \times n)$ matrix that holds the counts of every pair of consecutive courses. Every pair of courses (i, i') that a student has taken consecutively is used to estimate the entry $\mathbf{F}_{i',i}$, i.e., the frequency of the event that state $\mathcal{A}_{i'}$ follows the state \mathcal{A}_i . For example, consider student Anna in Fig. 1. The entry corresponding to the course pair of (MATH1000, CSCI1111) will be updated. Similarly, every line connecting two courses will equally contribute in the corresponding element of matrix \mathbf{F} .

After we compute the frequencies of matrix \mathbf{F} , we need to normalize it to get \mathbf{T} , a row stochastic matrix, so that the total transition probability from state i to any other state

will sum up to 1:

$$\mathbf{T}_i = \mathbf{F}_i / \sum_{i'=1}^n \mathbf{F}_{i,i'}, \text{ if } \sum_{i'=1}^n \mathbf{F}_{i,i'} > 0.$$

Additionally, it is possible that the sum of some rows to be zero. This occurs when a course is taken at the last semester of every student, so there are no courses after that to pair it with. In that case, we set the diagonal elements of the zero rows to one; $\mathbf{T}_{i,i} = 1$ and $\mathbf{T}_{i,i'} = 0$ for $i \neq i'$, if $\sum_{i'=0}^n \mathbf{F}_{i,i'} = 0$.

4.3 Walking over courses

We can view the Markov chain in the context of random walk on a course-to-course graph that is governed by the transition probability matrix. A random walk on a directed graph will form a path of vertices generated from a start vertex by selecting an edge, making a step by traversing the edge to a new vertex, and repeating the process [4]. This concept has been applied to many scientific fields. Closer to this work, random walks have recently been used for top-n item recommendation [19], and they are also known to empower systems used in production at major social media platforms [12, 8].

A random walk starts with any probability distribution $\mathbf{u} \in \mathcal{R}^{1 \times n}$. \mathbf{u}_i is the probability of starting at vertex i . If one starts at a vertex i , then $\mathbf{u}_i = 1$, else $\mathbf{u}_{i'} = 0$ for $i' \neq i$. In our setting, the random walk for student j will equally start from any course in the student’s last semester, so the personalization vector will be:

$$\mathbf{u}_i = \begin{cases} 1/|\mathcal{C}_{j,t_j}| & \text{if } i \in \mathcal{C}_{j,t_j}, \\ 0 & \text{otherwise.} \end{cases} \quad (1)$$

Let $\mathbf{p}^t \in \mathcal{R}^{1 \times n}$ be a row vector with an element for each vertex specifying the probability of being there at time t . Before we start the walk, $\mathbf{p}^0 = \mathbf{u}$. After the first step, the probability of being at vertex i' is the sum over each adjacent vertex i of starting at i and taking the transition from i to i' . In matrix notation, when we are at state k and we take a step, we will get the following probability distribution:

$$\mathbf{p}^{k+1} = \mathbf{p}^k \mathbf{T}, \quad (2)$$

where the i -th entry of the \mathbf{p}^{k+1} is the probability of the walk after $k+1$ steps to land at vertex i . This can be written as a function of the starting probability vector as:

$$\mathbf{p}^{k+1} = \mathbf{u} \mathbf{T}^k. \quad (3)$$

The probability of the walker to reach the vertices after K steps provides an intuitive measure that can be used to rank the courses and offer personalized recommendations to the student accordingly.

Scholars Walk

To introduce an additional way for personalization in our model, we perform a *random walk with restarts* [21]. We introduce a parameter α , $0 < \alpha \leq 1$ that controls if the walk will take the step described above, or if the walk will restart. In the latter case, we use the personalized probability distribution as the restarting distribution. The probability dis-

Algorithm 1 SCHOLARS WALK

Input: Model \mathbf{T} , student's personalization vector \mathbf{u} , parameters α, β , number of steps K .
Output: Recommendation vector \mathbf{p}^{rec} .
 $\mathbf{p}^0 \leftarrow \mathbf{u}, k \leftarrow 0$
repeat
 $k \leftarrow k + 1$
 $\mathbf{p}^k \leftarrow \alpha \mathbf{p}^{k-1} \mathbf{T} + (1 - \alpha) \mathbf{u}$ \triangleright Take a step.
 $\mathbf{p}^k \leftarrow \mathbf{p}^k / \|\mathbf{p}^k\|_1$ \triangleright Normalize \mathbf{p}^k .
until $\|\mathbf{p}^k - \mathbf{p}^{k-1}\|_2 < tol$ or $k \geq K$
for $i \leftarrow 1$ to n **do**
 $\mathbf{p}_i^k \leftarrow \mathbf{p}_i^k * \text{pop}_i^{-\beta}$ \triangleright Penalize popular courses.
end for
 $\mathbf{p}^{rec} \leftarrow \mathbf{p}^k$

tribution now is defined as:

$$\begin{aligned} \mathbf{p}^{k+1} &= \alpha \mathbf{p}^k \mathbf{T} + (1 - \alpha) \mathbf{u} \\ &= \mathbf{p}^k (\alpha \mathbf{T} + (1 - \alpha) \mathbf{1} \mathbf{u}) \\ &= \mathbf{u} (\alpha \mathbf{T} + (1 - \alpha) \mathbf{1} \mathbf{u})^k, \end{aligned} \quad (4)$$

where $\mathbf{1}$ is a column vector ($n \times 1$) of ones. The product of $\mathbf{1} \mathbf{u}$ will give us an $(n \times n)$ matrix where every row will have the probability that the walk will start at the corresponding course. Scholars Walk will perform a random walk governed by the matrix $\alpha \mathbf{T} + (1 - \alpha) \mathbf{1} \mathbf{u}$.

The exact steps we followed are shown in Alg. 1. We can specify the number of steps to perform, or we can allow the algorithm to converge. If the number of steps is very small, the walk might not explore enough courses. If the number of steps is large, the walk might travel too far, and the recommendations might not be so relevant for the student. Additionally, to limit the domination of popular courses, we penalize the probabilities with the term $\text{pop}_i^{-\beta}$ [5], where pop_i is the popularity of the course. The parameter $\beta, 0 < \beta \leq 1$ shows how harsh we need to be with the penalty term.

Scholars Walk allows us to consider direct, as well as, transitive relations between the courses. It also provides a considerable degree of personalization, in order to recommend courses that are relevant to each particular student.

5. EXPERIMENTAL DESIGN

5.1 Competing approaches

The baselines are two group popularity approaches, on the department level (**Pop1**) and the academic level (**Pop2**) of the student measured by the number of years in the program [9]. For Pop1, we recommend the most popular courses in the major. For Pop2, we recommend the most common courses on the major and the academic level of the student ("freshmen", "sophomores", "juniors", and "seniors"). Students after their fourth year are considered seniors.

We also compared against Basic Markov model (**Markov**) and Basic Markov model with skip (**MarkovSkip**) [15]. In these models, for a target student, the set of courses that other students have taken after taking a course that the target student took are the possible courses to recommend. We consider the combination of courses during the last two

semesters to build and test the model. Each course is assigned a recommendation score that is the sum of all the conditional probabilities that lead to that course starting from the student's enrollment in the last semester. While the counts used in this case are the same with the ones computed in our matrix \mathbf{F} , the conditional probabilities are computed differently. In order to produce recommendations for students whose set of prior courses did not have a match, the skip model was introduced. In that case, we find other students that have similar course history with the target student, and weight their corresponding probabilities by a parameter λ .

Last, we train an **LSTM**-based course prediction model similar to [17, 23]. LSTMs can learn temporal dependencies with additional gates to retain and forget selected information. As input, we use a multi-hot representation of course enrollments per semester which are mapped to a predicted sequence of vectors. Once the LSTM has been learnt, we feed the network with a binary vector that indicates the courses that the target student has taken the past semester. The weights at the output of the model are used to rank the courses.

5.2 Evaluation metrics

Like in prior work [9, 15, 17, 23], we used **Recall@ n_s** as the primary evaluation metric for the predictions, where n_s is the number of courses that the student took in the target semester. This is the percentage of actual enrolled courses that were contained in the recommendation list. The reported metrics are averaged out across all students predicted. Note that recall and precision are equivalent in our setting, since we recommend exactly as many courses as the student will take the upcoming semester.

We also compute the percentage of queries for which we were able to retrieve at least one of the courses that the student took in the target semester (**%rel**). It measures for how many cases we were able to recommend at least one course that was relevant.

5.3 Experimental setting

Model selection. Using the dataset described in Sect. 3, we split it into train, validation and test sets as follows. All semesters before 2013 (about 10 years) were used for training, courses taken during 2013 and in Spring 2014 were used for validation, and courses taken afterwards (Fall 2014 to Spring 2017) were used for test purposes, to report the results. The training set was used for building the models, whereas the validation set was used to select the best performing parameters in terms of the highest Recall@ n_s . Based on the best set of parameters for the validation set, we computed the test set results in Sect. 6.

Parameters. For parameter α , we tried the following set of values: {1e-4, 1e-3, 1e-2, 1e-1, 0.2, 0.4, 0.6, 0.7, 0.8, 0.85, 0.9, 0.99, 0.999}. For parameter β , we tested values from 0 to 0.8, in increments of 0.025. In terms of the number of steps that we allowed for our walker, we tested the values 1, 3, and 1000. The last value corresponds to no limit for the number of steps.

Additional filtering. We build a different model for each

Table 3: Results for Scholars Walk w.r.t. K .

K	Recall@ n_s	%rel	α	β	avg#steps
1	0.466	75.1	0.955	0.047	1
3	0.460	74.6	0.088	0.053	1.95
1000	0.461	74.6	0.075	0.051	2.32

K is the number of steps that we allow to our walker. α, β columns show the average values of these parameters over the models of all the majors.

The last column shows the actual average number of steps the Scholars Walk made before convergence.

Table 4: Performance comparison.

Model	Recall@ n_s	%rel
Pop1	0.336	62.5
Pop2	0.338	64.6
Markov	0.456	73.0
MarkovSkip	0.400	69.6
LSTM	0.406	69.6
Scholars Walk	0.466	75.1

major for all the approaches we tested. After we generate a ranked list of the courses using any method, we filter out courses that are not offered the target semester. We also remove courses that the student has taken in the past and achieved a grade above C-, as they do not count towards any degree requirements, as mentioned in Sect. 3. In the end, we return a list with as many recommendations as the number of courses, n_s , that the student took next semester, based on assumption 5.

6. RESULTS

In this section, we will try to answer the following questions: 1) How do the parameters in our models affect the overall performance? Specifically, how does the number of steps affect recommendation performance? 2) What is the performance of our approach compared to the state-of-the-art approaches?

6.1 The effect of the number of steps

The performance of our models in terms of the metrics computed for different values of K is shown in 3. For each model and selection of K , we see the values of the parameters α and β that were used. These parameters were selected based on the recall on the validation set. The parameter α controls the restarting probabilities, while β is used to re-weight the probability distribution before recommending its highest-weighted courses. The column avg#steps shows the average number of steps that the Scholars Walk actually made before convergence.

In this domain, we need only a few steps, as we can understand from Table 3: not only when we set $K = 1$ we get the best performance, but also, when we allow the walk to take many steps, the parameter α gets smaller values. This forces the walk to go back to the student’s personalized starting vector with higher probability, indicating that the starting distribution is very important. Additionally, even if we do not put any constraints in K , the number of steps that the

Scholars Walk takes is quite small. There is a small increase when increasing K from 1 to 3, but after that, the number of steps actually taken is not that high.

It is worth pointing out that, while setting $K = 1$ gives us the best overall performance, this is not the case for all the departments. The right value for K depends on the dataset used. In our data, there are four departments that need these extra steps. We observed that these departments have low average course popularity, which is average percentage of students that have taken a course at least once at some point during their studies, over all the courses. The average value for the departments with $K > 1$ was $16.7 \pm 9.7\%$, while for the rest of the models the corresponding number is $24.1 \pm 7.2\%$. A stronger signal is present in the metric of the degree flexibility, which is the average Jaccard distance between the courses that any pair of students took, as defined in the end of Sect. 3. The departments with $K > 1$ have 0.118 ± 0.005 degree flexibility against 0.184 ± 0.066 of the rest of the departments. This is an indicator that for stricter degrees, the walk depends on the extra steps to explore more courses. In these departments, students will take overall very similar sets of courses. On the other hand, if the degree program offers more freedom to the students, they select a wider range of courses, and there are more connections within courses.

6.2 Performance comparison

By comparing the best Scholars Walk model against five competing approaches, we get the results on Table 4. Our model performs the best, both in terms of recall, and in the percentage of cases for which it manages to be return some relevant recommendations.

Popularity approaches are having considerably satisfactory performance. However, specifying the academic level of the student does not help much. They can recommend relevant courses to more than 60% of the cases. The two Basic Markov models have quite different performance. The Markov model with skips performs poorly, compared to the Basic model. Additionally, it is worth mentioning that the Skip model was performing better and better as the parameter λ was getting smaller. The weight of the cases that do not completely match the target student’s history, have as weight a power of λ . Consequently, when $\lambda \rightarrow 0$, the Skip model becomes the Basic Model. For that reason, the smaller value of λ that we report results for, is 0.4.

While comparing the Basic Markov model with Scholars Walk, it may seem that they have similar performance. However, that might be misleading, as the Basic Markov model utilizes longer course enrollment history than the Scholars Walk. It looks back two semesters on the student’s courses, which corresponds to a second-order Markov chain. Moreover, the model uses data from two semesters not only for computing the associated probabilities, but also to make predictions. This leads to increased complexity because of the larger state-space with no benefit in recommendation quality. In the same boat are the LSTMs as well. Their increased complexity might lead to the overfitting of the model, when the data are not sufficient for training. Our approach, which is a first-order Markov chain, manages to perform better than the higher-order models and LSTMs.

Scholars Walk can accurately predict the course selection of the students, by taking advantage of the “breadth and depth” of the data. In terms of time complexity, once we build the transition probability matrix, walking through the courses is trivial. As a result, it scales well with the number of students, while providing them personalized recommendations. At the same time, it is a white-box model, where the recommendations are easily explainable.

7. CONCLUSION

In this paper we propose Scholars Walk, a novel method designed to harvest the sequential patterns arising from past course enrollment data in order to recommend a short list of personalized course suggestions for the next semester. The proposed method relies on a random walk-based scheme on a course-to-course graph and personalization is achieved by a student-adapted starting distribution reflecting the current student’s enrollments. When compared with five competing models, from popularity-based to LSTMs and Basic Markov models, Scholars Walk achieves the best performance. It manages to be a successful, scalable approach that provides personalized recommendations for every student.

ABSTRACT

Short forms of psychometric scales have been commonly used in educational and psychological research to reduce the burden of test administration. However, it is challenging to select items for a short form that preserve the validity and reliability of the scores of the original scale. This paper presents and evaluates multiple automated methods for scale short form creation based on metaheuristic optimization algorithms that incorporate validity criteria based on internal structure and relationships with other variables. The ant colony optimization (ACO) algorithm, tabu search (TS), simulated annealing (SA) and genetic algorithm (GA) are examined using confirmatory factor analysis (CFA) of scales with one factor, three factor, and bi-factor factorial structure. The results indicate that SA created short forms with best model fit for scales with one and three factor structures, but ACO was able to obtain highest reliability. For scales with bi-factor structure, SA provide short forms with best model fit, but TS obtained highest reliability. Overall, the SA algorithm is recommended because it produced consistently best model fit and reliability that was only slightly lower than the ACO or TS algorithms.

Short form development, confirmatory factor analysis, metaheuristic algorithms, validity, ant colony optimization, tabu search, genetic algorithm, simulated annealing

1. INTRODUCTION

Applied researchers using psychometric scales often face a dilemma due to limited resources: should they use the full form of a well-established scale with strong validity evidence supporting it, but with a large number of items requiring a substantial amount of time and effort to complete, or should they use a short form of the scale that has not had the extensive evidence of validity? This issue has generated strong interest in the academic community the development of short forms of scales (e.g. [1]). Multiple methods have been proposed for scale short form development [2], with different fields utilizing a few preferred methods. For example, these methods include theoretical or practical justifications for the

inclusion or exclusion of items (e.g., [3]), keeping one item from a set of items that are apparently similar or redundant (e.g., [4]), obtaining certain criteria for statistical values such as high factor loadings or item correlations (e.g., [5]), adding or retaining items that seem to improve measures of reliability and/or dimensionality (e.g., [6]).

The focus of item selection for short forms tends to be on the internal structure of the newly-created form, rather than using external relationships to help build the short form. For example, Petrillo, Capone, Caso, and Keyes [7] created a short form for a positive mental health assessment for use with Italian respondents by selecting items from twelve other scales with a focus on its internal structure. The resultant short form had adequate psychometric properties, but the average absolute correlation between the total score and sixteen other criterion measures was 0.37 (range: 0.20 to 0.62). Despite the adequate validity evidence for the internal structure, the external relationships would be characterized as modest since on average the short form's and the other measures' scores shared about 6% of their variances.

Obtaining a short form that has both adequate internal structure and strong validity with respect to relationships with other variables is difficult with traditional methods of short form development. Metaheuristic optimization algorithms [8] have the potential to solve these difficulties because they can simultaneously maximize multiple validity criteria for short forms. This paper aims to present the evaluation of multiple automated methods for short form creation based on metaheuristic optimization algorithms that incorporate criteria based on internal structure and relationships with other variables and determine which perform best under commonly used scale structures.

2. THEORETICAL FRAMEWORK

There have been some attempts to develop algorithms to derive short forms of scales that (a) maintain the internal structure of the scale in question (e.g. factor structure and/or content balance), (b) have favorable model characteristics such as meeting model fit statistic thresholds, and (c) produces scale scores that have favorable relationships with other variables, including other scales or external variables. For example, Olaru, Witthoft, and Wilhelm [9] compared multiple algorithms for the purpose of creating psychometrically valid short forms of a 99-item scale with various criterion (e.g., jointly optimizing two fit indices) and concluded that, under their study conditions, the Ant Colony Optimization (ACO) and Genetic Algorithm (GA) were able to produce statistically appropriate short forms that generalize well to new data. Marcoulides and Drezner [10] have shown that a Tabu search

Anthony Raborn, Walter Leite and Katerina Marcoulides "A Comparison of Automated Scale Short Form Selection Strategies" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 402 - 407

can be used to successfully reduce the number of items loading on factors. Leite, Huang and Marcoulides [2] developed and demonstrated an ACO algorithm that selects items for short forms while keeping adequate model fit and maximizing the relationship between the latent variable and external variables. More recently, Browne, Rockloff, and Rawat [11] produced an automated structural equation modeling (SEM) scale reduction algorithm and purport that it is an effective and efficient method for reducing items during scale development.

While these articles demonstrate the use of some automated scale short form development strategies and the importance of research in this area, an in-depth comparison of automated strategies under different scenarios does not seem to exist. In addition, some commonly-used metaheuristic algorithms for combinatorial problems have never been applied to the short-form development problem. For example, the inaugural example of the simulated annealing (SA) algorithm is with the Traveling Salesman Problem, which has various algorithms attempt to find the shortest path that travels between n cities exactly once [12], while no psychometric use of SA is apparent in the literature. To address these issues, this paper presents a simulation study utilizing three different scale structures commonly observed in educational research (one factor, three factor, and bifactor scales) and four meta-heuristic algorithms: The ant-colony optimization algorithm (ACO), genetic algorithm (GA), Tabu search (TS), and simulated annealing (SA). We chose these algorithms because they are the most well-established metaheuristic algorithms in the combinatorial optimization literature.

The ACO algorithm [13] mimics the behavior of ants searching for the shortest path to a food source. We evaluate the implementation of the ACO algorithm proposed by Leite, Huang and Marcoulides [2] for short form development, with minor modifications to the tuning parameters. Their implementation of the ACO algorithm attaches sampling weights to items, which are used to sample items for a set of candidate short forms of the scales. Each set of candidate short forms is evaluated and the best short form in the set is identified based on criteria that are specified by the researcher, such as SEM fit indices and the relationship between the scale's factors and an external variable. The criteria of choice are used to calculate the pheromone level, which is a summary of the quality of the short form chosen. The pheromone level is then used to update the sampling weights for the next round of sampling of candidate sets of short forms. This is repeated until a specified convergence criterion is met, such as number of iterations without improvement of the solution quality.

The GA mimics the biological process of evolution using the model parameters as genes. As implemented by Yarkoni [14], the algorithm generates an initial population of candidate models of size 200 and, by evaluating the fitness of each candidate model through a loss function, selects the best 20% of the models and repopulates. Between model generations, new models are created from mutation (randomly changing the items in a model) and recombination (two models exchanging items retained). After a certain number of iterations (100+), the model with the best fit according to the loss function is retained as the best solution. The loss function penalizes the fit of the models for every item included; this value needs to be tuned to achieve the correct reduction of items.

The TS algorithm implementation was modified from the presentation given in Marcoulides and Falk [15] to constrain the solution space to a specified number of items. Broadly, the TS looks at each of the local solutions to a model by changing one model

parameter at a time; the particular change can be adjusted to suit the problem at hand. The main idea behind the TS procedure is to continually adjust the currently selected best model by examining other models in the neighborhood of the current best solution. If a neighboring model fits better than the current model, it is selected as the new best fitting model. If not, the examined neighboring model is marked "tabu"—placed on a list so that it is not reconsidered for some number of iterations. For this study, the TS was modified to (a) randomly generate a short form of a predetermined length from a longer form for the first iteration and (b) search for local short forms that maintain the predetermined length.

The SA algorithm is a statistical analog to metallurgic processes of annealing metals [16]. Generally, the algorithm begins with a specified starting model whose parameters are randomly changed by some process and a starting temperature. The new model is compared to the starting model and the difference in model fit is calculated. At any time, if the new model has better fit than the current model, it is selected for use in the next iteration; otherwise, the new model is selected with probability equal to a function of the difference in model fit and the current temperature. After each new model is either selected or ignored, the temperature updates and the current model is randomly changed. The algorithm checks each model against the best model seen and updates as needed. Some variants of the algorithm include a process that selects this best model after a certain number of iterations in which no better model has been found. This process repeats until the temperature reaches zero.

3. METHODS

3.1 Research Questions

1. How do the algorithms differ in terms of the time it takes for each to converge on a short form, model fit and reliability of the short form?
2. How do model misspecifications in the full form affect the fit and reliability of the short forms created by the algorithms?
3. Does the inclusion of an external variable affect the model fit and reliability of the short forms?
4. Does the performance of the algorithms depend of the factorial structure of the scale?

3.2 Manipulated conditions

To investigate the research questions, a Monte Carlo simulation study was conducted using the following population confirmatory factor analysis models: (a) the 20-item unidimensional model of the self-deceptive enhancement (SDE) scale [17], (b) the 24-item three-dimensional model of the teacher efficacy scale [18], and (c) a three-factor bifactor model [20] of the 30-item BASC-2 BESS [19] scale. These models represent three common models seen in scale development and are good representations of what educational researchers would work with. The covariance structure from the multidimensional scale were used to simulate samples for these conditions, and the factor loadings for the unidimensional model were used to simulate samples for this condition. In each case, the goal was to create a short form that is half the length of the long form.

Additional manipulated simulation conditions were the relationship with an external variable and full-scale model misspecification. For the relationship with an external variable, the two levels that were manipulated are (a) no relationship and (b) a moderate relationship (approximately equal to a path coefficient of 0.6 standard

deviations). The full-scale model misspecification was manipulated in the simulation according to three levels: (a) no misspecification, (b) a minor misspecification in the factor loadings (i.e., population models modified to have six of the items cross-loading on a nuisance factor with a loading of 0.3), and (c) a major misspecification in the factor loadings (i.e., same as (b), but with factor loadings of 0.6 on a nuisance factor).

The data were simulated in R v3.5.0 [21] using the ‘MASS’ package [22]). The baseline condition (i.e., high reliability, no external variable relationship, no misspecification) used the values provided by the original models as the population values. These values were changed as necessary to create new population models that fit the target simulated conditions, resulting in fifteen covariance matrices. The sample size of each condition was set to 500. For each combination of manipulated conditions, we created 100 datasets.

3.3 Outcomes

The outcome variables of the simulation were the time to converge to a short form, the average level of model fit of the short form, and the composite reliability of the short form for each factor.

The comparative fit index (CFI), Tucker-Lewis Index (TLI), and Root Mean Square Error of Approximation (RMSEA) were used as the model fit indices, and the cutoff values of CFI > .95, TLI > .95, and RMSEA < .05 were used as indicators of adequate model fit [26].

For this study, the composite reliability of the one and three factor models was calculated as [23]:

$$CR_{\omega} = \frac{(\sum_{i=1}^I \lambda_i)^2}{(\sum_{i=1}^I \lambda_i)^2 + \sum_{i=1}^I \theta_i}$$

where the items are indexed with i , λ are the standardized factor loadings, and θ are the (standardized) residual variances of the items [24]. For the bifactor model, the composite reliability for the of general factor was calculated as

$$CR_{\omega_h} = \frac{(\sum_{i=1}^I \lambda_{gi})^2}{(\sum_{i=1}^I \lambda_{gi})^2 + \sum_{i=1}^I ((\sum_{s=1}^S (\lambda_{si})^2) + \sum_{i=1}^I \theta_i)}$$

where s indexes the specific factors [25].

4. RESULTS

For each factor model, results for the “Minor Error with External Variable” condition did not have noticeable differences from either the “Minor Error with No External Variable” conditions or the “No Error” conditions, so this condition was dropped from the current study.

4.1 One Factor Model

The time to complete for each algorithm was similar across conditions, except for GA (see Table 1), which was faster. The time to converge was slightly longer for the ACO, SA, and TS under the major error with an external relationship condition.

The average model fit statistics for both factor models across 100 replications of the analysis for the three conditions is also shown in Table 1, where bolded values indicate good model fit. When there is no error in the original model, each algorithm produced good model fit, but as the error level increases the model fit decreased.

In the major error conditions, only the SA algorithm had model fit greater than the traditional cutoff values.

Table 1. Model fit of short forms for one factor model

Error/ External	Method	Minutes to Complete	CFI	TLI	RMSEA
None/ No	ACO	2.482	0.976	0.969	0.043

Major/ No	ACO	2.713	0.943	0.926	0.061
	SA	2.581	0.983	0.978	0.029
	TS	3.956	0.940	0.923	0.061
	GA	0.701	0.850	0.807	0.112
None/ Yes	ACO	3.059	0.943	0.929	0.058
	SA	2.871	0.981	0.976	0.029
	TS	2.819	0.923	0.903	0.066
	GA	0.702	0.859	0.823	0.106
Major/ Yes	ACO	3.301	0.942	0.928	0.058
	SA	3.107	0.981	0.976	0.029
	TS	5.162	0.934	0.917	0.060
	GA	0.752	0.855	0.819	0.108

The inclusion of the external variable reduced the model fit for each of the algorithms such that the conditions with no error and an external variable relationship had similar fit to the conditions with major error and either with or without external variable relationship (see Table 1).

Table 2 shows the reliability of the full form of the scale, as well as the reliability the short forms. As expected, the full form resulted in scores with higher reliability than all the short forms. The ACO had the greatest composite reliability for both the no error and minor error conditions, followed by the GA.

Table 2. Composite reliability estimates with one-factor model

Method	Reliability
Full Form	0.889
ACO	0.854
SA	0.813
TS	0.806
GA	0.835

4.2 Three Factor Model

For all five conditions, the SA and TS algorithm took about twice as long to converge on average as compared to the ACO and GA algorithms (see Table 3). For the three-factor model, the average model fit for the conditions with no external variable can be seen in Table 3. In both the no error and minor error conditions, each of the algorithms had good model fit. In the major error conditions, only the SA algorithm produced short forms with adequate model fit according to all three fit indices. The ACO and TS algorithms

had good model fit according to CFI and TLI (ACO) and CFI (TS), while the GA algorithm had poor fit according to all three fit indices.

Table 3. Model fit for short forms with three-factor structure

Error/ External	Method	Minutes to complete	CFI	TLI	RMSEA
None/ No	ACO	2.967	0.979	0.973	0.043
	SA	6.228	0.991	0.989	0.024
	TS	6.063	0.986	0.982	0.031
	GA	2.705	0.977	0.970	0.044
Minor/ No	ACO	3.091	0.978	0.971	0.047
	SA	6.238	0.989	0.985	0.030
	TS	6.264	0.984	0.979	0.037
	GA	2.710	0.974	0.967	0.048
Major/ No	ACO	3.285	0.964	0.953	0.054
	SA	6.295	0.990	0.987	0.027
	TS	6.061	0.956	0.943	0.056
	GA	2.695	0.910	0.883	0.087
None/ Yes	ACO	3.713	0.978	0.971	0.047
	SA	7.040	0.989	0.985	0.030
	TS	7.577	0.984	0.979	0.037
	GA	2.685	0.974	0.967	0.048
Major/ Yes	ACO	3.387	0.960	0.948	0.060
	SA	6.173	0.984	0.979	0.036
	TS	6.586	0.950	0.935	0.063
	GA	2.282	0.917	0.892	0.087

Including an external variable had little effect on the model fit indices (see Table 3). With no error, the average model fit was approximately the same between the no external variable conditions and moderate external variable conditions, while the average model fit somewhat decreased in the major error condition for the external variable conditions as compared to the no external variable conditions. Only the SA produce short forms with good model fit across all the conditions.

The reliability of the full form and short forms with the three-factor CFA is shown in Table 4. All methods produced short forms with less reliable scores than the full form, but among the metaheuristic methods, the ACO produced short forms with the largest composite reliability for each of the factors in each condition.

Table 4. Composite reliability estimates with three-factor model

Method	Reliability Factor 1	Reliability Factor 2	Reliability Factor 3
Full form	0.870	0.910	0.900
ACO	0.788	0.846	0.833
SA	0.752	0.829	0.813
TS	0.754	0.828	0.809
GA	0.763	0.846	0.819

4.3 Bifactor Model

With the bifactor model, the GA had the fastest time to converge, and the ACO took about four times longer. The TS and SA algorithms had convergence times that were about 10 times of the GA algorithm.

Table 5 shows the average model fit indices of the bifactor model for the conditions with no external variable relationship. The SA and TS algorithms produced short forms with good model fit by each fit index in every condition, while the ACO resulted in good model fit by each fit index except for the RMSEA in the major error condition. The GA had good model fit by CFI in the no and minor error conditions only.

Including the external variable tended to reduce model fit. Both the SA and TS showed slight reductions in model fit across both error conditions, but still found short forms with good model fit according to all three fit indices. The ACO maintained approximately the same model fit in both no error and minor error conditions, but showed an increase in average fit in the major error conditions when comparing the no external variable to moderate external variable relationship conditions. However, only the CFI and TLI showed good model fit in these conditions (see Table 5).

The reliability of general factor with the full form and short forms with the bi-factor model are shown in Table 6. For the example scale used in this study, the full form produced scores with adequate reliability for the general factor, but for the specific factors the composite reliability is low. For the short forms, none of the algorithms produced consistently greater reliabilities for every factor in these conditions. The reliability of general factor with the short forms were smaller than the reliability of the full form for all algorithms. The GA performed best for the general factor reliability than the ACO, SA and TS.

Table 5. Model fit of short forms with bi-factor model and external variable

Error/ External	Method	Minutes to complete	CFI	TLI	RMSEA
None/ No	ACO	13.054	0.986	0.976	0.041
	SA	37.925	0.995	0.992	0.020
	TS	39.933	0.992	0.986	0.028
	GA	3.577	0.951	0.939	0.074
Minor/ No	ACO	12.296	0.982	0.969	0.047
	SA	40.658	0.994	0.990	0.023
	TS	48.200	0.990	0.984	0.031
	GA	3.562	0.954	0.943	0.069
Major/ No	ACO	12.875	0.974	0.956	0.055
	SA	39.556	0.993	0.987	0.027
	TS	41.211	0.982	0.969	0.043
	GA	3.606	0.945	0.921	0.079
None/ Yes	ACO	18.537	0.986	0.976	0.041
	SA	45.815	0.995	0.992	0.020
	TS	49.665	0.992	0.986	0.028
	GA	3.458	0.951	0.939	0.074
Major/ Yes	ACO	17.989	0.975	0.959	0.051
	SA	42.336	0.991	0.986	0.028
	TS	38.947	0.979	0.965	0.046
	GA	3.546	0.940	0.907	0.080

For the specific factors, the TS performed better than the other methods for two out of three factors. Surprisingly, the TS produced scores with higher reliability than the full form for factor 3, and the SA produced higher reliability than the full form for factor 2.

The results with the bi-factor model are limited in that the scale used produced scores with low reliability. Using a different scale that results in higher reliability of scores of the full form for all factors might have produced different results with respect to the comparison of algorithms.

Table 6. Reliability of short forms of general factor of bi-factor model

Method	General Factor	Factor 1	Factor 2	Factor 3
Full	0.715	0.304	0.114	0.319
ACO	0.661	0.067	0.115	0.062
SA	0.641	0.061	0.133	0.055
TS	0.659	0.149	0.124	0.433
GA	0.669	0.055	0.118	0.049

5. CONCLUSION

In general, the algorithms produced short forms with adequate model fit in all cases with no error, with two exceptions: each algorithm except the SA under the one factor model with an external variable, and the GA under the bifactor model. Therefore, when the original scale is correctly specified, the results showed that the algorithms are likely to produce short forms with model fit that maintain the desired factor structure of the scale.

The ACO, TS, and GA each had problems maintaining good model fit for the short forms with increasing error, though this was alleviated by increasing the factor structure's complexity. Including an external variable into the process generally had a small negative effect on average model fit, but the effect was never enough to cross the model fit thresholds. Overall, the SA provided short forms with the best average model fit in every single condition, while the ACO seemed to have better reliability on average for each of the factors with one factor and three-factor models. Given that the difference in reliability between the ACO and SA algorithms was about .05 or less on average, the practical difference in reliability between these methods may be outweighed by the difference model fit of the resulting short forms. Therefore, the current results lead to recommending the SA as the preferable metaheuristic algorithm for automated short form selection.

This study provides useful information to applied researchers about the benefits and drawbacks of utilizing these four algorithms for scale short form development in some common scenarios in educational research. This will allow for easier creation of psychometrically-sound short forms with stronger evidence of validity, especially as compared to creating short forms manually. Future research could apply these algorithms to the short form creation problem alongside other methods on real data to compare the efficacy of each approach.

ABSTRACT

Creativity is a dynamic process which generates ideas that are both novel and of value. However there is little understanding in what drives creativity in students and how to help teachers or education experts to detect creative thinking. This paper begins to address this gap by providing a platform and experiments for studying how creative outcomes can ensue over time. The platform is an open ended environment for creating geometrical shapes that supports exploration and trial and error. We show that participants exhibit diversity in their usage patterns in the system, and in particular, some exhibiting 'creative leaps' in which they move from creating a sequence of shapes in one category to another, new category. We designed a visualization tool that aids understanding in detecting these aspects in students' work. We provide a basic computational model that is able to predict whether a student will create a new shape at a given point in time. The impact of this work is in beginning to provide tools for promoting creativity in students and directing their interactions in a way that facilitates the creative process.

Keywords

Creativity, Divergent Thinking, Geometry, Geogebra

1. INTRODUCTION

There is multiple evidence that exhibiting creativity in the classroom is linked to positive learning gains, and using educational technology to bring about creativity is an active area of research [19, 8]. To date, however, such technologies have relied on human teachers to detect and to promote creative behavior. While research on adaptive technologies for education have flourished, there are few studies on automatically detecting creativity from students' interactions.

This paper begins to address this gap by providing a platform for studying and computationally modeling creative tasks. The task requires participants to create geometric

shapes and explore multiple solutions in a domain that is simple to define and explain, while still providing a rich space of possible solutions.

The task was chosen so that there is no single correct answer, and the goodness of a solution is measured by the number and quality of the different answers. This task supports a process of exploration and discovery. There are many possible strategies for solving the tasks, some requiring more skills than others.

We study people's search trajectories in the space of possible solutions, showing that people exhibit creative leaps [9], alternating between clusters of solutions and exploration. We adapt a model by Leikin [10] for measuring creative outcomes in users' interactions, based on defining their work in terms of flexibility, originality and fluency. We provide a visualization tool that decomposes a user's interaction sequence in the system to separate sequences of solutions. When a creative leap occurs, the solutions in the inferred sequence belong to the same class.

We show that people's creative outcomes in the system varies widely, in a way that depends on the creative leaps that are exhibited by the participants. We built a computational model that attempts to predict whether or not a given shape is new for a given participant. We define several sets of features that include statistics about shapes created as well as GUI operations used to create the shapes. The best performance was achieved by a random forest classifier that was based on both features.

These results can potentially inform the design of algorithms for detecting and promoting creative outcomes.

The remainder of this paper is organized as follows. In the next section we provide a general description of the creativity testbed for creating geometric shapes. We then describe a tool for visualizing the shapes created by individual users over time, and how to cluster these shapes in a way that can detect creative leaps. Finally we provide a computational model for detecting new shapes in a user's interactions, and discuss ways to extend this model to detect creative outcomes.

2. RELATED WORK

Previous research showed that creativity is linked to positive learning gains, and using educational technology to bring

Roi Shillo, Nicholas Hoernle and Kobi Gal "Detecting Creativity in an Open Ended Geometry Environment" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 408 - 413

about creativity is an active area of research [19]. While these programming environment support interactions that can lead to creative thinking, they rely completely on human teachers to detect and to promote this behavior.

We focus on the use of technology to promote divergent thinking, which is a type of creative ability that generates multiple answers to problems [18, 6]. Guilford [6] defines divergent thinking as generation of multiple answers to a problem. Torrance[17] defined fluency, flexibility, novelty, and elaboration as parameters that describe divergent thinking. Fluency is the ability to create large number of ideas for a problem that are useful. Flexibility is the ability to change direction, thinking strategies and point of views. Originality is the ability to generate novel and unconventional ideas. Unconventional ideas defined as statistically infrequent.

There are several works focusing on the use of technology to promote creative outcomes in students. Multi Solution Tasks (MST) is mathematics open ended problems with multiple correct answers that can reached in different ways [12]. MST improves the participant's understanding and the connection between his knowledge domains, skills and strategies [4]. Levav-Waynberg & Leikin [12] found that MSTs raised the connection between knowledge domains in geometry, and improve the fluency and flexibility of the participants. Geometry plays a major role in Math teaching. It includes visual, abstract and logical skills. Geometry created opportunities for investigation, generalization, deduction and gives autonomy to the learner to explore mathematics with his personalized preferences [12, 3].

Sophocleous & Pitta-Pantazi [16] found that using software environment for geometry enhanced the creative abilities of students by facilitating them to provide more, different and unique solutions.

Noy et al. [15] demonstrated the role of creative leaps in two dimensional geometry. They show that human players exhibit two types of exploration: 'scavenging', where similar shapes are accumulated, and 'creative leaps', where players shift to a new region in the shape space after a prolonged search. They show that the network of shapes created by human participants is different from the class of networks created by applying a simple random-walk algorithm. We extend their work in two ways. First by providing a computational model to detect new shapes; second in extending the notion of creative leaps to a framework that allows a richer set of actions to be created. In subsequent work they studied creative exploration using a scale invariant model that considers relative changes in signals [7].

There are few studies on automatically detecting creativity from students' interactions. An exception is Manske and Hoppe [14], who have used supervised learning methods to detect creativity in programming assignments that require mathematical skills. They combined low level features (e.g. code snippets) with higher level features (e.g., the use of recursion, number of lines of code) to train numerical predictors and predicted a creativity score for new solutions. Chuang et al.[2] used fuzzy logic to detect student's creativity measures in a gaming environment. Loveless et al.[13] studied the use of technology to promote aspects of cre-

Figure 1: Open Creativity App

ative thinking for student teachers, including the development of new ideas, modifying and evaluating the originality and value of work as it develops. These works relied on manual approaches for detecting creativity and did not study how to visualize these creative outcomes.

3. THE GEO CREATIVITY TESTBED

We designed an activity (built as a GeoGebra app) in which participants create geometric shapes by manipulating the shaded area that intersects two rectangles (See Figure 1).

Participants can employ geometric transformations on each rectangle according to several possible actions supporting by the testbed GUI: Translation (shifting a rectangle along the x or y axis), rotation (re-positioning the rectangle by changing one or more of its angles), re-sizing (increasing or decreasing the size of both of the rectangles). Creating different shapes requires to master different skills. It is easier to create polygons of varying number of sides by rotating the rectangles, but other types of shapes requires more steps, using more actions or have a precise positioning of the rectangles in designated angles.

To help with the positioning, participants can optionally choose to display the angles formed at the vertices, the length of the intersection shape sides, or position the two rectangles perpendicularly one to each other. At any point in time, participants can choose to submit their shape to a gallery. When the shape submitted to the gallery, the interface doesn't change and the participants continue their work from the same point.

The GUI design supports several key factors that have been shown to facilitate creative outcomes in students. First, it provides an open ended task in which there is no single correct answer, and the goodness of a solution is measured by the number and quality of the different answers [10].

Second, the task supports a process of exploration and discovery. Participants can manipulate two rectangles to create new shapes. Trial and error is a key part of the exploration process [5].

Third, understanding the task does not rely on complex or unique tool set. Participants with little knowledge in geometry can use the task and think about novel and useful categories. Participants with more knowledge and experience will have a better potential to think about new and

Figure 2: Categories Distribution over Participants

unconventional categories [1].

Fourth, there are many strategies to create shapes from the same category. Some requiring more skills or using more tools than others. For example, squares can be created by rotating and positioning the two rectangles, and also by using “perpendicular rectangles” option in the GUI menu [1].

This task is recommended activity by content developers for K4-K5 students that learn geometry. The idea is for students to learn to generate geometric shapes in a novel way (intersecting the two rectangles). The number of possible shapes that students can create with the system is not bounded.

3.1 Procedure

We recruited 183 Participants (87 undergraduate students and 96 Mturk workers with varying educational background - high school, Bachelor and master graduates). All participants needed to pass a tutorial and comprehension quiz about the study in order to participate.

All participants were requested to “create as many different polygons types as possible by intersecting two rectangles.” Students performed the task as part of an extracurricular activity and were not monetarily compensated. Participants in Mturk received monetary compensation as follows: 30 cents as a show up fee and 10 cents for every type of shape that they’ve created.

The task was limited by 10 minutes, and on average participants spent 4.5 minutes on the task.

Participants created between one and ten different shape categories (e.g., Polygon, square, etc.) and 1445 shapes in total. Figure 2 shows the frequency of the shape categories submitted by users to their portfolio. The x axis denotes the shape category; the blue bars display the number of shapes that was created for each category (values in the left vertical axis). The red line shows the percentage of participants that created shapes of the given category (values in the right vertical axis).

As shown by the figure, the most popular shape categories were Pentagon, Hexagons and “other” Quadrilaterals (quadrilaterals which were not rhombus, square or rectangles). The least popular shape categories were septagon, square and rectangles. There was a general correspondence between the number of times a shape was created and the number of users who created the shape. However, some shapes cat-

Figure 3: Visualization tool showing timeline of shapes (top), and shape sequences (bottom) for user ID 752

egories, namely Rhombus, square and rectangle, were more popular. For example, the Rhombus is the fourth most popular shape category, yet it is the second most popular shape among the users. We will show later that these shapes played a special part in people’s creative process.

3.2 Visualization Tool

We designed a visualization tool for studying how individual participants create shapes over time. Fig 3 shows the main interactive panel in the visualization system. The main panel shows the shapes created by an individual user (ID 752). The x axis represents time (in seconds) from commencement of the interaction, while the y axis represents the length of time (in seconds) it took to create shapes. For example, the coordinate (30, 4) shows the first shape created by the user (Rhombus) at time 30 and took 4 seconds to create. As shown in the figure, participant ID 752 created 11 shapes over a time span of 230 seconds. We can see that the participant exhibited high variance in the creation time of the shapes. For ease of analysis, there is a way to group shapes into temporal sequences according to the following criteria: First, a sequence has to include at least n contiguous shapes. Second, the probability that the next action belongs to the same sequence is greater than a designated threshold T . The threshold can be set in a way that maximizes the number of shapes in the sequence. A shape i commences a new sequence if $P(\frac{\Delta_i - \mu}{\sigma}) > T$ where Δ_i is the length of time spent to create shape i , μ and σ are the average time and standard deviation for creating shapes by the participant. In this way we consider the extent to which the creation time of each shape agrees with the individual participant (assuming a normal distribution over creation time).

Figure 3 shows four shape sequences that were created by the user, inferred by the criteria described above. We can see that sequence II and IV are relatively short and include shapes that share a common category (that of trapezoids or

hexagons, respectively). In contrast, sequence I and III are longer and include shapes of different categories. We next show how these sequences yield insights into creative aspects of the shape creation processes.

3.3 Measuring Creativity

We measure the creativity of a participant following Torrance [17] who defined dimensions of flexibility, fluency and originality to describe creative solutions to problems: Fluency is the number of solutions that was proposed by the participant. Flexibility is the number of strategies that the participant applies for the solution. Originality is statistically infrequent ideas that were produced by students relative to their classes or groups.

We calculate the score by the formula suggested by Leikin [11], adapted to the geometry app. The flexibility of a shape i is 10 if the shape is new for this participant, or 1 otherwise. The originality of a shape i is 10 if the shape was chosen by fewer than 15% of participants (septagons), 1 if the shape was chosen by between 15% and 40% of participants (rectangles and squares), and 0.1 if the shape was chosen by more than 40% of participants.

The fluency of a shape is always 1. Let n be the number of shapes created by the participant (also the participant's fluency score). The creativity score of a participant is computed as $\sum_{i=1}^n FX_i \cdot OR_i$ where FX_i and OR_i are the flexibility and originality of shape i .

4. CREATIVE LEAPS

Participants exhibited a diverse range of creativity scores in their work. The average score was 80 with a standard deviation of 54. To explain differences between students, we need to analyze the dynamics of how shapes were created. We will distinguish between two types of shape creation, those representing exploration in the space of possible concepts, and those representing exploitation of one of the concepts that is used to create shapes.

Koestler [9] describes a creative leap as the moment where a new dimension of possibilities appears. The creative leap signifies a point in the search space in which the learner discovers a new class of solutions and begins to exploits this space by creating shapes.

In sequence II and IV of participant 752 (shown in Figure 3) the participant exploits the concept of trapezoid and of hexagons, completing two shapes in each category. Both of these sequences represent creative leaps. In contrast, sequence I and III for this user represents exploratory behavior in which the participant does not converge on a shape category. In particular, sequence IV commenced 81 seconds after the last shape, suggesting a lengthy process of exploration leading to the next shape category.

We use the concept of creative leaps to distinguish between different types of participants, as determined by their interaction in the system.

Another example, participate 651 holds an MA degree, exhibited a creativity score of 128, with fluency of 36, flexibility of 8, and originality of 1 (rectangle and square). Participant

Figure 4: Shape sequences for low scoring participant ID 655 (left) and high scoring participant ID 651 (right)

Figure 5: New and old shapes

655 holds a high school diploma, with a creativity score of 61, with fluency of 5, flexibility of 4 and originality of 1 (rectangle and square).

Figure 4 shows the shape sequences for these two participants. As shown by the figure the users exhibited drastically different interaction styles with the system. The low scoring participant (user ID 655) created only five shapes, which can be described by 4 sequences. Only sequence I for this user consisted of shapes of a similar category. In contrast, the high scoring participant (user ID 651) created 36 shapes, which can be described by 10 sequences (for brevity we only show the first four). Five of these sequences included shapes with particular categories.

5. COMPUTATIONAL MODEL

Using the creation of a new shape as a proxy for creativity, we build a computational model that attempts to predict whether or not a given shape is new for this participant. This is a first step for detecting creativity for this participant. To this end, we extract a number of features and use logistic regression and a random forest classifier to predict the binary outcome of whether or not a given shape is new for the user.

Figure 5 shows the layout of new shapes (green) and old shapes (blue) for users across time. It demonstrates that while the proportion of new shapes being generated certainly does decrease as the user continues to interact on the platform, there are a significant number of shapes that are created 'later' on in the user's interaction session. These shapes

Figure 6: Plots showing the raw shape coordinates and the extracted actions from the database. Top is a resize action where both input rectangles are affected. Bottom is a rotation action to the second rectangle

are new to the user and can signify the commencement of a creative leap.

5.1 Feature Extraction

The raw data represents individual coordinates of the two input rectangles where the user can rotate, translate and resize the two rectangles. We extract changes to these coordinates to represent the 5 actions that the user can perform on the system. Figure 6 shows the primary actions that a user can perform. The resize action affects both shapes simultaneously whereas the user can perform rotate and translate actions to each shape individually.

As a number of actions are preformed before a user submits a shape, we include the history of actions in the feature matrix considering a maximum of 15 actions before the shape was submitted; 95% of shapes were submitted with less than 15 steps. We aim to infer whether including the history of actions provides additional information to a model predicting the creation of a new shape. In other words, our goal is to determine if combinations of actions are predictive of a new shape and thus indicative of certain creative insights.

5.2 Method

Given four feature sets, we use cross-validated logistic regression (LR) and random forest (RF) classification to predict the binary classification problem of whether or not the shape is new for the user. Other classification techniques were explored including support vector machines, boosted decision trees and naive Bayes classifiers but LR and RF were chosen for simplicity and the ease of interpretation into the parameter coefficients (or feature importance in the RF). Moreover, LR allows the application of an L1 sparsity regularizing parameter to induce sparsity in the feature space (thereby assisting inference). The available features are:

Table 1: Different combinations of available features that the four feature sets used.

Feature Set	Shape History	Action History	Aggregated Action History
Feature set 1	Y		
Feature set 2	Y	Y	
Feature set 3	Y		Y
Feature set 4	Y	Y	Y

1. **Shape History.** Counts of previously submitted shapes from the user for each of the 10 shape categories.
2. **Action History.** A one-hot encoded representation of actions in 15 previous steps leading into the shape creation. Following the actions shown in Figure 6 there were 3 possible actions (translate, rotate or resize) at each step. We further include a 'control' action that represents a recorded step but no action. This case might occur when the user does not interact with the shapes but rather interacts with a different UI element or possibly performs an administrative action such as submitting the shape. This creates 60 features in total for each instance.
3. **Aggregated Action History.** The sum of the **Action History** features across the 15 steps. This results in 4 additional features per instance describing the number of times each action was performed. For example, a vector (2, 3, 5, 5) corresponds to 2 translate, 3 rotate, 5 resize and 5 control actions (in any order).

The three sets of available features were aggregated in different combinations to provide four feature sets that were used for evaluation. Table 1 summarizes the different combinations that were used.

5.3 Results

Our goal was to determine if certain sequences and/or combinations of actions are predictive of the user generating a new shape. Table 2 summarizes these results. We note that the Feature Set 3 provides a slight improvement over the baseline of Feature Set 1 for both LR and RF. Feature Set 4 with RF shows the greatest accuracy with a 2% increase over the baseline feature set. The results are reported from a 10 fold cross-validation but the predictive increase is not significant across the folds. The results suggest that the inclusion of the action data does assist slightly with the predictive performance of the model but we note the result is not conclusive. However, analyzing the feature weights of the LR for Feature Set 3 and the RF for Feature Set 4 is illuminating.

It is interesting to note that the RF model with the temporal features outperforms the LR on these same feature sets. Again, although the results are not significant they do suggest there is a more complex interaction of the action history of the user that might be predictive of the new shape creation. Further investigation into how **sequences** of actions might be indicative of the creation of a new shape (and thereby indicative of a creative leap) is needed to answer this question definitively.

Table 2: Table showing the results from the prediction task of predicting a new shape for a given user.

Feature Set	Accuracy	
	LR	RF
Trivial all 0 prediction	59.9%	59.9%
Feature set 1	75.5%	75.4%
Feature set 2	74.8%	76.1%
Feature set 3	76.0%	76.5%
Feature set 4	73.5%	77.5%

6. CONCLUSION AND FUTURE WORK

We presented an approach for studying creativity using a web based tool in which participants created geometric shapes. This task supports a process of exploration and discovery, allowing people to exhibit creative leaps in which they transition between different areas of the search space of possible solutions. We adapted a model by Leikin for measuring creative outcomes in users' interactions. We collected data from multiple people interacting with the system showing that they vary widely in terms of the creativity they exhibit. We built a visualization tool that decomposes a user's interaction sequence in the system to separate sequences of solutions. We built a computational model that attempts to predict whether or not a given shape is new for a given participant. We define several sets of features that include the number and categories of shapes that were created by the user, as well as basic actions performed by the users in the system for a window of activity. The best performance was achieved by a random forest classifier that was based on both features. In future work we intend to extend the computational model to detecting creative outcomes in new types of domains.

7. ACKNOWLEDGMENTS

The authors would like to thank Yuval Hart for very useful discussions and advice; Sara Hershkovitz, Guy Hed and Shoshana Gilead from the Center of Education Technology, for developing the task, their pedagogic support and helping with the coding; Adar Slonim and Ahmad Majadly for development help.

ABSTRACT

Prior research has shown that, under certain conditions, Human-Agent (H-A) alignment exists to a stronger degree than that found in Human-Human (H-H) communication. In an H-H Second Language (L2) setting, evidence of alignment has been linked to learning and teaching strategy. We present a novel analysis of H-A and H-H L2 learner dialogues using automated metrics of alignment. Our contributions are twofold: firstly we replicated the reported H-A alignment within an educational context, finding L2 students align to an automated tutor. Secondly, we performed an exploratory comparison of the alignment present in comparable H-A and H-H L2 learner corpora using Bayesian Gaussian Mixture Models (GMMs), finding preliminary evidence that students in H-A L2 dialogues showed greater variability in engagement.

Keywords

Language learning, chatbot, dialogue, alignment, tutoring, agent, second language, student engagement, assessment

1. INTRODUCTION

This work reports on evidence of alignment within student dialogue to that of an automatic tutor even when both parties are restricted in their capacity to align: the student as an L2 learner may lack the linguistic proficiency to show alignment [5], and the agent aligns only minimally by design. Alignment consists of interlocutor interaction adaptation, resulting in convergence, or in their sharing of the same concept space [13, 8]. Alignment of student to tutor in dialogue has been used as a predictor of both student learning and engagement [20]. A key aspect of dialogue is

the speakers' ability to align: to either show engaged, willing behaviour, or display little discernible adaption to their interlocutor. Interestingly, humans have been shown to exhibit greater alignment to agents than to other humans [4, 6]. In an automated L2 tutoring setting, where students have been shown to imitate tutors as part of their learning process [10] it is of great interest to determine whether the user/learner is actively engaged, simply gaming the system, or disengaged, either because of lack of ability or motivation [1]. Modelling alignment of student to tutor as evidence of engagement could serve as a useful tool in the design of tutor intervention or student assessment since there has been limited research into identifying signs of engagement or gaming in the automated L2 tutoring setting.

Given this relevance of alignment in modelling engagement during tutor-student L2 dialogues [20], one key question is whether L2 students demonstrate alignment behavior in conversation with an automated dialogue agent, even when they know the agent is not human. Prior work has established that L2 students display alignment when conversing with a human tutor, in Human-Human (H-H) interactions [17]; however, this work has also demonstrated relatively *symmetric* alignment, as human tutors verbally aligned with their students in turn — this raises the possibility that L2 learners may fail to display alignment if the dialogue is predominantly *asymmetric*, when interacting with an agent whose capacity to align is also limited. Studies of Human-Agent (H-A) dialogues in other domains demonstrate that fluent speakers verbally align with agents [4, 6], but given the unique constraints affecting alignment in L2 dialogue [5], we cannot assume that L2 students will behave similarly. If they do, a second key question arises: do L2 students display similar alignment behavior in H-H and H-A dialogues? Even if students align in both contexts, exploratory analysis may reveal critical differences which could inform educational researchers and practitioners working with dialogue agents. Hence, our work addresses the following research questions: **RQ1** *Do L2 students show alignment to an automated dialogue agent (i.e. H-A alignment)?* and **RQ2** *What is the nature of the alignment found in the H-A corpus and how does it differ from that of H-H dialogues?*

Arabella Sinclair, Kate McCurdy, Adam Lopez, Christopher G. Lucas and Dragan Gasevic "Tutorbot Corpus: Evidence of Human-Agent Verbal Alignment in Second Language Learner Dialogues" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 414 - 419

We present a study of student verbal alignment within a new dialogue corpus consisting of transcripts from a language teaching app where students are interacting with a dialogue agent. We contrast this H-A corpus with a comparable H-H L2 learner corpus of tutoring dialogue transcripts. We found that students in H-A interactions align to the agent more so than they would by chance, albeit to a lesser degree than students in H-H dialogues. Our results found that within H-H dialogues, students exhibited greater alignment than tutors. Finally, we compared the distribution of student to tutor alignment within both corpora, revealing more variance in alignment within the H-A dialogues. We hypothesise this was due to either student engagement effects, or different types of student alignment strategy within the H-A dialogues than the more uniform alignment present in the H-H corpus.

2. BACKGROUND

To achieve effective communication within dialogue, speakers typically align, adapting their interaction to their interlocutor. The Interactive Alignment Model (IAM) [13], describes this process as that of speakers agreeing on a shared conceptual space. In educational settings, by contrast, alignment has been found to predict both student learning and engagement [20]. Automatic alignment between interlocutors occurs over different linguistic levels, including that of the lexical, syntactic and semantic [13]. *Lexical* alignment consists of speakers beginning to use the same words [21, 17] or phrases [6] as each other. *Syntactic* alignment consists of the use of the same parts of speech patterns, such as similar noun-phrase constructions, or similar adjuncts [14] as the conversation progresses. Finally, *semantic* alignment can range from adaptation to individual differences in personality [11] to convergence at a higher level of representation such as Dialogue Acts [16]. Recent research has established a number of metrics for linguistic alignment which can be computed automatically, enabling large-scale corpus analysis based on sequential pattern mining [6]. These methods quantify alignment in terms of the *expressions*, or contiguous sequences of tokens appearing in the utterances of both interlocutors. While these methods have been applied to the analysis of H-A interaction [6] and H-H student-tutor interaction [17], the work presented in this paper is the first to apply this computational methodology to compare H-A and H-H dialogue in an educational L2 setting.

Within an L2 practice setting, we predict alignment to have slightly different properties compared to a fluent conversational setting where speakers tend to have a symmetric contribution and equal status within the dialogue [18], and are equally capable of participating [5]. L2 learners have been found to perform at a higher level when speaking in dialogue with a peer than in a monologue context [15]. This suggests students draw from the example language of their interlocutor leading us to expect evidence of alignment. L2 students have also been shown to learn vocabulary through taking part in dialogue [9], suggesting this process of alignment and repetition of their interlocutor's speech produces learning gains. In the case of the tutor, their need to adhere to the ZPD suggests that their alignment patterns will also differ from that of straightforward dialogue. These different factors influence the speakers' convergence to a shared mental state [5]. Vygotsky's theory of ZPD [19] states students

Table 1: Tutorbot dialogue example. Italics indicate Expression Repetition

1.	bot:	What is your <i>favorite day of the week</i> ?
2.	user:	My <i>favorite day of the week</i> is Friday ...
3.	bot:	Do you play sports ?
4.	user:	yes
5.	bot:	What sport do you <i>play</i> ?
6.	user:	I <i>play</i> volleyball and I go running
7.	bot:	When do you do that ?
8.	user:	On Monday , Wednesday and Friday
9.	bot:	What time does it start ?
10.	user:	At 4 o'clock in the afternoon

will learn best when addressed at the correct level, therefore we also expect to see alignment, in the case of tutors in H-H dialogues, to student ability.

3. CORPORA

We are interested in the comparison between student alignment in H-H and H-A dialogues. The H-A corpus analyzed in this study comprises dialogues drawn from a large-scale commercial platform for L2 learners¹. In this application, novice learners of English who had completed lessons on relevant topics were offered the possibility to review the material via simple conversations with the automated dialogue agent Tutorbot. Given the focus on relevant learning material, the agent engaged learners in a system-initiative dialogue with extensive guidance, rather than user-initiative [2]; as a result, Tutorbot steered the learner conversations very deliberately, and alignment from the tutor agent to the student was highly limited by design. A sample dialogue from the corpus can be seen in Table 1. The H-H corpus used is the Barcelona English Language Corpus (BELC) [12] which consists of tutor guided conversations with L2 learners of English at varying stages of fluency from absolute beginner to approaching intermediate. The tutor's goal was to elicit as much conversation from the learner as possible while setting them at ease in as natural and conversational a manner as they could. Key differences are shown in Table 2. However, it should also be noted that the Tutorbot corpus only consists of single utterance turns, whereas BELC has multiple. The topics are also more diverse in BELC, as the Tutorbot explicitly guided learners to review practiced material rather than engage in open-ended discussion. Nevertheless, certain main topics (*how are you, where are you from, tell me about your family, hobbies, what time do you do that*) and the beginner/lower-intermediate range of learner ability are common to both, facilitating automated alignment comparison.

4. METHODS

4.1 Alignment

In order to analyse the verbal alignment present in both corpora, which allows us to answer both *RQ1* and *RQ2*, we use the expressions-based measures introduced by [6]. This approach identifies sequences of tokens (*Expressions*) which are used by both dialogue participants (thus *established* as expressions). These expressions allow us to see the fixed expressions established between speakers, called the routiniza-

¹This data was kindly shared with us by Babbel, <https://www.babbel.com/>

Table 2: H-A and H-H Corpora Differences

	Tutorbot	BELC
number of dialogues	3689	118
average Num. utterances	20.41	130.69
average Num. tokens	128.99	634.28
average tokens/utterance	6.32	4.85
communication medium	typed	spoken
speakers	H-A	H-H
student L1	German	Spanish
vocabulary overlap	0.085	0.251

tion process in the interactive alignment theory [13], and thus an indication of speaker alignment. We re-define the following in order to discuss our results in the following sections:

Expression Lexicon EL is the set of expressions used by both speakers for a given dialogue.

Expression Variety (EV) is the size of the EL normalised by the total number of tokens in the dialogue. This ratio indicates the variety of the expression lexicon relatively to the length of the dialogue: the higher the EV, the more incidence of established expressions between participants. The EV indicates the routinization between speakers.

$$EV = \frac{\text{length}(EL)}{\text{number of tokens}}$$

Expression Repetition – speaker (ER_S) is the ratio of Expressions to dialogue produced. This is measured in tokens. This value indicates the Expression repetition present in the dialogue, i.e. the higher the ER, the more the speakers dedicate tokens to the repetition of established expressions. This is indicative of speaker alignment.

Initiated Expression (IE_S) are the established expressions initiated by S

Vocabulary Overlap (VO) is the ratio of shared tokens between interlocutors S₁ and S₂. The higher the VO, the more vocabulary is shared between speakers.

$$VO = \frac{(\text{Tokens}_{S_1} \cap \text{Tokens}_{S_2})}{(\text{Tokens}_{S_1} \cup \text{Tokens}_{S_2})}$$

4.2 Baseline

In order to test that the alignment reported was not simply due to corpus-specific vocabulary effects (which would be influenced by the vocabulary overlap defined in the previous section), a ‘scrambled baseline’ was created for each corpus. This was achieved by creating a ‘bag of words’ of the tokens produced by each speaker for a specific dialogue, then substituting each token from each speakers utterances with one from the shuffled bag of words. This method retains the turn-taking of the speakers, and the distribution of utterance lengths from the original dialogue, but removes any word ordering present. In the results section for each alignment measure, we report on whether the effects were significantly different from this baseline. This baseline allows us to compare the effects of alignment across corpora, answering *RQ1*.

4.3 Alignment Distribution Clustering

In order to answer *RQ2* investigating student alignment differences within and between the H-H and H-A corpora, we fitted a Gaussian mixture model (GMM)[7] to the student ER_S data for both the H-H and H-A students. GMMs allowed us to detect and characterize distinct sub-populations within a larger group, provided those sub-populations were marked by differences in a parameter of interest, e.g., measured ER_S. To find the number of components which best fitted the data, we used a Bayesian Gaussian mixture model with a Wishart prior of $[[0.1]]$ on the precisions and a scale-1 exponential prior on the number of clusters, and selected the most probable number of clusters given the data (i.e. the posterior mode), assuming that up to seven clusters might be present. We used a Bayesian approach in order to avoid the degeneracies that are common when using maximum-likelihood estimation and information criteria (e.g., AIC or BIC) to estimate cluster counts and parameters [3]. To implement this, we used the toolkit scikit-learn², package *BayesianGaussianMixture*; the priors on component means were scikit-learn 0.20 defaults.

5. RESULTS AND ANALYSIS

The following subsections all contribute to answering *RQ1*, through the comparison of H-H to H-A student alignment and corpus statistics. Section 5.5 specifically explores the variation in alignment styles across corpora, allowing us to answer *RQ2*.

5.1 Expression Lexicon

The Expression lexicon is the set of expressions which are shared between speakers. On inspection, the most common multi-word expressions being aligned to in the Tutorbot corpus fell into two main categories: 1) the student using the direct re-form of the question in the creation of their answer: “*bot|4: What **is** your **favorite day of the week** ? user|5: My [**favorite day of the week**] [**is**] **Friday**”.* 2) The student reflecting the question back to the tutor-bot. “*bot|4: Where **do you live**? user|5: I live in <LOCATION>, where [**do you live**]?”*. The rephrasing in BELC is different: it is more likely that the tutor will re-phrase the student’s single or multi word answer as a form of confirmatory feedback. e.g. “*Tutor: you like going out with your friends, good*” when this is really more repetition/confirmation. The student alignment also consisted of their reflection of tutor questions back to them, and in their repetition of tutor scaffolding moves (something not present in the Tutorbot corpus due to the agent dialogue design) Table 3 contains details of the vocabulary overlap, speaker specific token ratios and the expression lexicon size differences between corpora.

Table 3: Corpora Differences- values represent the average per dialogue

	Tutorbot	BELC
Expression Lexicon Size (ELS)	3.04	48.55
S1/tokens (%)	0.81	0.68
S2/tokens (%)	0.19	0.30
Voc. Overlap	0.085	0.251
Voc. Overlap S1	0.105	0.312
Voc. Overlap S2	0.258	0.613

²<https://scikit-learn.org/stable/>

5.2 Vocabulary Overlap

The vocabulary overlap (VO) between speakers gives us an idea about how likely ‘alignment’ according to our metric will occur by chance. The results in Table 3 therefore can inform our interpretation of the levels of ER_S reported in section 5.4. Student VO in BELC (HH) is much higher than from the students in Tutorbot (HA) (0.613 vs. 0.258). This could be due to the fact that Tutorbot learners were at a lower level of proficiency, so they did not use such extensive vocabulary; alternatively, it could be due to the method of data collection: Tutorbot allows learners a one turn response (a single utterance), limiting their production.

Figure 1: H-H/A corpora Vocabulary Overlap. Speaker difference was significant for H-A ($p < 0.0001$) ($statistic = 6.42, pvalue = num1.4e - 10$) and H-H ($p < 0.001$) ($statistic = -2.11, pvalue = 0.00036$) S1 = Tutor/Agent, S2 = Student

5.3 Expression Variation

We compare the H-H and H-A corpora of real interactions to each other, and to the baseline H- H_R and H- A_R corpora to control for vocabulary effects. Firstly, EV was significantly higher for the H-H corpus ($mean = 0.075, std = 0.025$) than that in the H-A corpus ($mean = 0.032, std = 0.046$). Statistical difference was checked by performing a t-test ($statistic = -10.05, p - value = 1.888 \times 10^{-23}$), indicating H-H interactions result in a richer expression lexicon than H-A interactions. The EV values were much lower than those reported for negotiation dialogues [6], which may be due to dialogue type: routinisation may form a much greater part of negotiation than it does L2 tutoring. Another reason for the low EV in the H-A corpus is that the student cannot establish expressions other than by chance since the Tutorbot corpus is system-initiated and is not designed to align to the student’s responses. Neither the EV of the H-H nor the H-A corpus was statistically greater than the H- H_R and H- A_R baselines, which can be in part attributed to the high proportion of single-token expressions in both corpora, leading to greater likelihood of their existence in the scrambled baseline.

5.4 Expression Repetition

Expression repetition (ER_S) is the main indication of speaker alignment measured. Figure 2 shows the different degrees

Figure 2: H-H/A corpora ER_S . Speaker difference is significant for H-A ($p < 0.0001$) ($statistic = -44.91, pvalue = 0.0$) and H-H ($p < 0.0001$) ($statistic = -12.71, pvalue = 1.77 \times 10^{-28}$) S1 = Tutor/Agent, S2 = Student

of ERs for both the H-A and H-H corpora. The difference between the ERs of each speaker was significant for both corpora: H-A ($statistic = -44.91, p - value = 0.0$) and H-H ($statistic = -12.71, p - value = 1.770 \times 10^{-28}$). It is interesting to note the asymmetry between speakers for both dialogues. The tutor in the H-H dialogues had a significantly lower proportion of ER than the student, suggesting ER has less to do with teacher strategy as with learner strategy. We compared each ER_S with its ER_R for both corpora: for the H-A corpus, student ER_{S2} ($mean = 0.192, std = 0.235$) was significantly higher than that of $ER_{R,S2}$ ($mean = 0.134, std = 0.206$) ($statistic = -11.20, p - value = 6.593 \times 10^{-29}$). Meanwhile, tutor ER_{S1} ($mean = 0.016, std = 0.032$) was significantly lower than that of their scrambled baseline $ER_{R,S1}$ ($mean = 0.024, std = 0.037$) ($statistic = 9.865, p - value = 8.2012 \times 10^{-23}$) indicating the absence of alignment expected from an agent not designed to do so. For the H-H corpus, student ER_{S2} was not significantly different from their baseline $ER_{R,S2}$ ($statistic = 0.932, p - value = 0.352$), nor was tutor ER_{S1} ($statistic = 2.506, p - value = 0.013$). This can be explained in part by the fact that VO for the H-H corpus ($mean = 0.251, std = 0.061$) was significantly larger than in the H-A corpus ($mean = 0.085, std = 0.146$) ($statistic = -12.32, p - value = 3.089 \times 10^{-34}$).

5.5 Student ER Distribution

In answer to RQ2, we compare the distributions of per-dialogue ER_S values between H-A and H-H corpora. Figure 3 shows histograms of ER frequency for each corpus, which suggest there were multiple types of student alignment in the H-A corpus (a), in contrast to a single cluster of ER values for the H-H corpus (b). To quantify these differences in student alignment – and go beyond a comparison of averages which neglects the possibility of differences across individuals and dialogues – we fit a Bayesian Gaussian Mixture Models [7] (described in Section 4.3) to student ER_S values. The results of our model indicate that the most probable number of clusters, given the data (i.e., the posterior mode), was 5 for the H-A corpus (Figure 3a) and 1 for the H-H corpus (Figure 3b). This analysis also reveals a

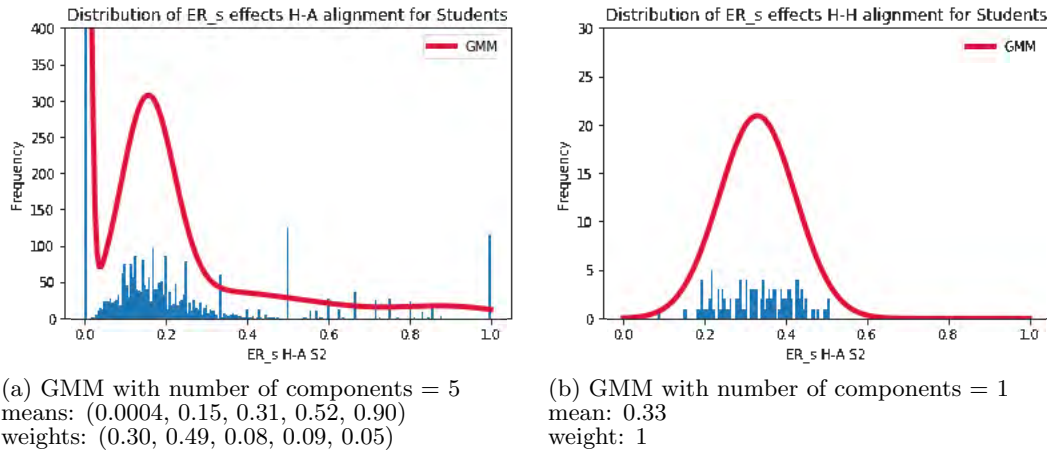

Figure 3: Frequency of Expression Repetition values (High ER indicates greater alignment). Gaussian Mixture Models (GMM) which best fitted to the data shown by the red line. Means: centroids of the component clusters. Weight: the proportion of dialogues in a cluster.

Table 4: Qualitative Analysis of H-A dialogues at the ‘centroids’ of the component clusters

ER	Description and example
0-0.01	no-response or request for help : students either do not engage with the agent, or demonstrate inability to engage
0.1-0.15	minimal response : students respond curtly, appear less engaged <i>bot: What is your favorite day of the week ?</i> <i>user: That 's Sunday .</i>
0.25-0.4	high engagement : dialogues either longer with align and rephrase within longer utterances, without excess repetition, or shorter dialogues consist of more repetition and rephrasing, and the limited vocabulary contributes to alignment <i>bot: Do [you] _have a_ boyfriend or _a_ girlfriend ? Or _a_ husband_ or _a_ wife ?</i> <i>user: I [have [a] husband] .</i>
0.5-0.55	minimal response : low rate of student production, typical response one high-frequency word, low engagement despite high alignment <i>'hi', 'bye.'</i>
0.85-0.9	high repetition : all student responses are rephrases, dialogues very short <i>bot: _Hello_ , _nice to see you_ !</i> <i>user: [Hello] [nice to see you] too</i>

cluster in the H-A corpus which has a qualitatively comparable mean value to the one in H-H (0.310-H-A, 0.330-H-H). Table 4, shows this cluster contains the longest dialogues in Tutorbot, which are qualitatively the most similar to those in BELC.

We hypothesise the other clusters are either, in the case of low level ER, signs of student lack of engagement (alignment being symptomatic of engagement within dialogue) or, in the case of higher ER, signs that the students are in some way conversing in a manner impossible to find in H-H dialogues. We hypothesise either this is due to the communication medium: students can copy, paste and edit the agent utterance to create their response or due to students’ desire to learn through continual repetition of the agent’s phrases.

Table 4 shows examples and descriptions of the H-A corpus data, corresponding to the component means in Figure 3. Since the H-H corpus was gathered as part of an experiment, we know that there would not be ‘outlier’ behaviour present, but the upper and lower ranges show some differences in interaction style of the learner.

6. DISCUSSION

In relation to *RQ1*, whether there is evidence of student - agent alignment in L2 dialogues, we find significant H-A alignment. The magnitude of this effect was weaker than that found in H-H dialogues, and we hypothesise that adaptive student support in the form of tutor alignment is essential for students to align to the degree they do in an L2 H-H setting. We found no significant alignment of agent to student, however an agent designed to interact with more explicit alignment may more resemble the alignment found in the H-H corpus. We found asymmetrical alignment within the H-H corpus, which was in keeping with results reported on lexical priming for the same corpus which found the strongest priming effects are those from student to tutor [17]. In relation to *RQ2*, concerning the exploratory analysis of alignment differences across corpora, a particularly salient finding are the differences in alignment across dialogues, suggesting different patterns of student engagement could be detected via their alignment levels. Table 4 shows that there was a clear ‘normal range’ for interaction, and the outliers showed different signs of student non-engagement. Our key finding is that there was greater variability in H-A compared to H-H alignment (best fit of 5 clusters compared to a single cluster), although role of factors such as dialogue and utterance length in these findings should be investigated in future work. We hypothesise that building a more alignment-focused tutoring agent could increase student engagement and yield results consistent to those within BELC. This could lead to better online L2 tutoring systems which promote student engagement and therefore improve participation and learning. It may be that the nature of an online learning platform will always result in some students who do not fully engage, and need different interven-

tion strategies. Using an alignment metric in the manner of our study could allow for the identification of these students, measurement of their engagement, and prediction of personalised interventions.

7. CONCLUSIONS AND FUTURE WORK

This paper presents a comparative analysis on student to tutor alignment in both an H-A and an H-H dialogue setting. We found students aligned to the agent, although this alignment was not stronger than that present in H-H dialogues which is the case for both negotiation [6] and task-based dialogues [4]. We hypothesise we can better explore this in a setting where the agent is specifically designed to align to the student. A limitation of our study is that both corpora were collected independently and therefore differ in more aspects than the one we wish to explore. In future work it would be desirable to collect data in a controlled setting which is more similar to the Tutorbot corpus to facilitate a more in-depth comparison. Another avenue for future research is the design of adaptive ‘alignment’ moves for the automated tutor to make. The design could draw on how the ZPD influences alignment and what the common ERs are in the H-H corpus, such as confirmatory rephrasing (e.g. “Student: I speak Germanish”, “Tutor: you speak **German**? Great!”) or repetition (e.g. “student: I am 20 years old”, “tutor: **20 years old**? good!”). This research has a number of implications for the educational community, particularly regarding the use of alignment as an indicator of engagement. Furthermore, our method of clustering student ERs to identify ‘normal’ engagement behaviour for a given domain may inform the detection of outliers and has potential for automating dialogue planning and intervention policies.

8. ACKNOWLEDGMENTS

We are grateful for the helpful discussions had with Nicolas Collignon, Edmund Fincham and Pablo Leon and comments from our anonymous reviewers. We thank the team at Babbel and specifically Zach Sporn and Joel Kiesey for making this collaboration possible.

ABSTRACT

We examine the ability of supervised text classification models to identify several discourse properties from teachers' speech with an eye for providing teachers with meaningful automated feedback about the quality of their classroom discourse. We collected audio recordings from 28 teachers from 10 schools in 164 authentic classroom sessions, which we then automatically transcribed into text utterances and then manually coded to identify whether: (1) the utterance contained a question (as opposed to a statement), (2) the question or statement was Instructional vs. Non-Instructional, and (3) the question or statement was Content-Specific. We experimented with Random Forest classifiers and engineered (linguistic, acoustic-prosodic, and contextual) features vs. open-vocabulary n-grams as features to discriminate these discourse variables at the utterance level in a teacher-independent fashion. We achieved AUC scores ranging from 0.71 to 0.77 using open-vocabulary language modeling, which were well above chance (AUC = 0.5), an important step towards our predominant goal of constructing of an automated feedback system for teacher reflection and learning.

1. INTRODUCTION

A teacher's ability to engage students in classroom instruction is of paramount importance in promoting greater student achievement and improving educational outcomes. The level of student engagement is highly dependent upon the ways a teacher interacts with students [1]. The nature of classroom discourse, consisting of the ongoing conversation between the teacher and students, may provide unique insights into a teacher's ability to engage students in the classroom.

Many defining characteristics of classroom discourse have been studied and documented [21]. Traditional methods of classroom instruction are typically presented as monologic discourse, usually in the form of lecture, recitation, and seatwork [20]. However, substantive engagement requires more than just passive listening from students; rather, it requires a degree of student involvement. Not surprisingly, the degree to which classroom

discourse is monologic vs. dialogic has been found to greatly influence student engagement, with higher ratios of student talk providing a necessary condition for improved engagement and dialogic interaction [15, 22]. In order to achieve more widespread classroom engagement, students must not only take notes or listen attentively to well-rehearsed lectures from an instructor but must also be engaged in meaningful conversations about a topic. This deep discussion, a hallmark of dialogic instruction [21], is characterized by a symmetrical balance between student and teacher speech, with social interaction shaping the instruction.

In addition to the ratio of teacher speech to student speech, other trends help to characterize dialogic instruction. For example, teachers who ask more questions tend to promote increased student interaction and discussion in classroom discourse [17]. To this note, the Measures of Effective Teaching Study (MET) found question-asking behavior to be a primary factor in the variability of teaching quality [13]. However, questions are not all created equally. Questions associated with classroom management (like attendance-taking or rhetorical questions which require no student response) are not expected to influence student engagement. Compared to informational questions with a known answer, questions which elicit open-ended responses from students are expected to promote increased levels of engagement [34]. These open-ended, or "authentic" questions, draw upon students' ability to put forth independent thought in forming a response, rather than simply perform an affirmation check of the right answer. Authentic questions also serve to initiate discussion in which students can more thoroughly explore an idea and consider different viewpoints [20]. This in turn helps improve their overall understanding and can increase interest in the subject [21].

Additional defining characteristics of dialog associated with increased engagement, and consequently achievement, include higher levels of uptake (teacher questions which incorporate student responses) and cognitive level (the level of cognitive functioning a teacher question seeks to elicit), among other factors [20]. The study by Gamoran and Kelly (2003) demonstrates the benefits of discussion-based approaches to classroom instruction, which contributed the most towards enhanced student performance on complex literacy [12].

Despite the positive correlation of indicators of dialogic instruction (such as authenticity, uptake, and cognitive level) with increased student engagement and achievement [22], the practice has not gained widespread adoption among teachers. Instead, traditional means of instruction and monologic discourse tend to be most prevalent in the classroom [29]. This might be attributed to the challenges encountered by teachers in adopting sustained dialogic discourse into their pedagogical practices. Most importantly, receiving and learning from feedback is essential to assess current abilities and identify areas for improvement. We know that providing teachers with training and data-driven

D'Mello "Utterance-level Modeling of Indicators of Engaging Classroom Discourse" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 420 - 425

analysis about their discourse has been shown to positively correlate with student achievement [16]. However, assessment of teachers' instruction via live classroom observations often provides evaluative rather than formative feedback [16]. Moreover, conducting these observations can be expensive, as they require skilled human judges, rubrics, training, and continuous assessment of observers [2]. Therefore, classroom observations occur infrequently, if at all, and must be augmented by additional approaches to further facilitate teacher improvement.

To address this challenge, our study derives from a larger multi-disciplinary project that aims to address a critical lack of quantitative and actionable feedback that teachers receive about the quality of their speech by providing an approach for the automatic analysis of teacher discourse. The present study works towards this overarching goal by automatically classifying teacher utterances from audio recordings of live classroom sessions.

1.1 Related Work

The study of automatic analysis of educational discourse has focused on areas such as online discussions [19], dialog-based intelligent tutoring systems [25], and cognitive models of student learning [5]. In this work we model teachers' classroom discourse through a fully automated process. We examine some of the recent findings in this area.

1.1.1 Modeling classroom discourse

Instructional segment (activity) classification. An instructional segment (or activity) provides coarse-grained information regarding what is occurring at the moment. For example, are students quietly doing seatwork, or is the classroom participating in a discussion or question and answer session? Wang et al. [28] investigated the use of automatic speech recognition of classroom discourse in order to provide feedback for teachers. The authors applied the Language Environment Analysis (LENA) system [11] to segment classroom recordings into broad categories (lecture, discussion, group work). Although the system could provide feedback about the ratio of student to teacher speech, it did not provide any qualitative information about the content or utility of the speech itself. Donnelly et al. [8] also examined automatic identification of instructional activities from classroom recording. Recordings of teacher speech were segmented into individual utterances and transcribed using automatic speech recognition. Using models trained on temporal, natural language, and acoustic features, the authors trained models to identify the dominant (76%) activities (question and answer, procedures and directions, supervised seatwork, group work, and lecture) with accuracies that easily outperformed chance baselines.

Utterance-level classification. At a finer grain than Instructional segment classification, Donnelly et al. [9] built on work by [3] to identify teacher questions within individual utterances. Classroom recordings were segmented, transcribed using Automatic Speech Recognizers (ASRs), and 218 acoustic, linguistic, and contextual features were derived. The acoustic features derived from 384 prosodic, spectral, and voice quality features extracted with the OpenSmile toolkit [10]. Then, a smaller set of 168 acoustic features was obtained by eliminating features with high multicollinearity using tolerance analysis. The transcriptions were analyzed for part-of-speech tags and the presence of specific words (e.g., *why*, *how*) to provide 37 linguistic features. A total of 13 contextual features included timing information, such as the duration of the utterance, the position of the utterance within the

class session, and the duration of the pauses preceding and following the utterance. The authors found that combination of all three modalities made no improvement over linguistic features alone in the task of question identification but did yield small improvements in non-question detection.

Session level classification. Given the positive association between the use of authentic questions and student engagement and achievement [1, 20, 21], any system seeking to provide automatic feedback needs to be able to automatically identify this variable. However, the infrequent use of authentic questions compared to other types of dialog leads to highly imbalanced class distributions that make classification tasks difficult [14]. For this reason, Olney et al. [23] aimed to detect the proportion of authentic questions over the course of the class session, rather than seek to classify individual utterances. Using a model trained on word, part-of-speech, syntactic, and discourse features, the prediction of class-level proportions ($r = 0.50$) outperformed aggregated utterance-level classification ($r = 0.27$), and these results were consistent across low and high dialogic classrooms, and on both ASR and human transcripts. In a follow-up study, Cook et al. [7] compared closed- and open-vocabulary techniques (described in Section 1.1.2) for the same task and found that both approaches were equally predictive of authenticity, but that averaging the models' predictions yielded significant additional improvements.

1.1.2 Computational techniques

We apply techniques from natural language processing and machine learning in the automatic analysis of teacher discourse.

Open-vocabulary language modeling. In contrast to hand-crafted feature sets, open-vocabulary language modeling dynamically generates features for machine learning models by obtaining counts of consecutive words (n-grams) extracted directly from the input text [27]. This "bag-of-n-grams" model then assigns each n-gram feature a value based on its frequency within each utterance. This approach lends itself to human-interpretable analysis of models (e.g., word clouds). Several hyperparameters might also guide the selection of n-grams derived from the training set that should be included in the set of features, as certain n-grams may be unimportant for models, such as n-grams that occur infrequently. These hyperparameters might include whether or not stopwords are removed from text, whether stemming is performed on words, and the types of n-grams considered (unigrams, bigrams, trigrams, etc.). In addition, pointwise mutual information (PMI), described in detail in [6], can be specified as a hyperparameter to filter n-grams by incorporating information about the collocations of words. The PMI for a given n-gram can be defined as $\text{pmi}(n\text{-gram}) = \log(p(n\text{-gram}) / \prod p(\text{word}))$ where $p(n\text{-gram})$ is the probability of an n-gram based on its relative frequency in the training data and $\prod p(\text{word})$ is the product of the probabilities of each word in the n-gram in the training data. This can help ensure only meaningful phrases (such as "*high school*") are used as features. Minimum document frequency might further guide the selection of n-grams (i.e. the n-gram must occur in a specified minimum percentage of all documents to be considered a feature). An overview of these techniques can be found in [6].

1.2 Novelty and Contribution

We apply natural language processing and supervised classification techniques for the *utterance-level* classification of multiple aspects of classroom discourse with an eye for providing

automated feedback to teachers. Our study is novel in multiple respects. First, with the exception of work on detecting individual questions, as noted in Section 1.1.1, existing analyses on the automatic classification of classroom discourse have focused on coarse-grained temporal information ranging from a few minutes to an entire class session. We hypothesize that fine-grained utterance-level information is needed in order to provide meaningful and actionable feedback. Therefore, this study analyzes classroom discourse at the utterance level.

The intrinsic value of a system for automated feedback to teachers is inherently dependent upon the ability to correctly classify *different types* of discourse from automatically segmented recorded speech. Whereas previous work has focused on identifying questions, the present approach considers several more specific discourse variables, which have not previously been studied using automatic recognition methods. In addition to question prediction, we also predict Instructional Questions and Statements as well as Content-Specific Questions and Statements. These discourse variables are described in detail in Section 2.1.2.

2. METHODS

2.1 Dataset

2.1.1 Data collection

Our dataset consists 167 recordings of class sessions, drawn from two sources. One source of data was collected in 2018 and consists of 127 observations from 16 teachers at three schools in western Pennsylvania. Additionally, we newly recoded a subset of the CLASS5 dataset, collected at seven schools in rural Wisconsin over 2014 to 2016. This source of data consists of 40 class observations from 11 teachers [8]. Teachers wore a wireless Samson AirLine 77 vocal headset which transmitted audio to a receiver to then be recorded on a laptop.

2.1.1 Utterance transcription using ASRs

The IBM Watson ASR [26] was used to automatically segment the class recordings into utterances based on hesitations in the audio stream, and to transcribe each resulting utterance. To evaluate the efficacy of the ASR, a sample of 20 utterances per class session was manually transcribed by human coders and these transcriptions were compared to the ASR transcriptions. The average word accuracy (W_{acc}) of the automatic transcriptions across class sessions was 0.602 when considering all utterances. The W_{acc} increased to 0.754 when considering only longer utterances that contained three or more words.

2.1.2 Coding of utterances and coding scheme

To prepare a labeled dataset for training supervised models, a subset of the transcribed utterances was selected for manual annotation by trained human coders. First, to generate this set, any two consecutive utterances were merged together if the pause between them was less than 1.0 seconds. This preprocessing step helped adjoin related phrases together and reduced the number of single word utterances. Next, 200 consecutive merged-utterances were randomly sampled from each class session. If a class session contained less than 200 utterances, then all utterances were sampled for that session. English and language arts content experts trained in the coding schema were given audio excerpts for each utterance in the sampled dataset. The coders manually annotated each utterance with several markers of classroom discourse. Because many of the annotated categories occur only infrequently in the dataset, some markers have been aggregated

together to form binary labels, such as Question or Non-Question. Below we describe the variables used in the current work.

Question/Statement/Fragment. Utterances were coded to determine whether they consisted of a question, statement, or fragment. Questions are defined as requests for information, while conversely, statements are utterances which do not request information. Rhetorical questions, such as, “*It’s the characteristic of a person, right?*” are not coded as questions because they are not requests for information. Fragments are a single word or a few words that have been separated from a cohesive statement or question in the ASR transcription and appear as an individual utterance. Fragments by themselves are meaningless, and it would not be useful to code their discourse properties. To perform binary classification, we combined statements and fragments to predict whether each utterance was a Question or Non-Question.

Instructional questions. Utterances identified as questions were further coded as Instructional or Non-Instructional Questions. Instructional Questions relate to the lesson and its learning goals, whereas Non-Instructional Questions are irrelevant to the lesson and its learning goals, such as questions about student movement and behaviors. For example, “*Who can tell me what a plot diagram is?*” would be coded as an Instructional Question, while “*Why are you late?*” would be considered Non-Instructional.

Instructional question type. Instructional Questions were further coded as Content-Specific, Generic, or Clarifying. Content-Specific Questions inquire about the content/disciplinary practices of the lesson and its learning goals, such as “*What is the theme of the poem?*”, or “*How do you typically revise?*”. Generic Instructional Questions are broad questions about organization, materials, behaviors, or checks for understanding connected to the lesson. Examples include “*Where is your paper from yesterday?*” and “*Does that answer your question?*”. Clarifying Questions are requests for restatements and repetitions, such as “*Can you say that again?*”. We combined the Generic and Clarifying codes to predict the binary classification of Content-Specific Questions vs. Non-Content-Specific Questions.

Instructional statements. Similar to Instructional Questions, utterances identified as Statements were coded as Instructional or Non-Instructional. Instructional Statements relate to the lesson and its learning goals, such as “*A character that moves the action forward but is not central to the story is a minor character*” and “*Today we are going to review literary terms that will be on the quiz on Thursday.*” Non-Instructional Statements are irrelevant to the lesson and its learning goals, such as statements about student movement and behaviors. For instance, “*You shouldn’t be walking around the room. Please sit down.*” In addition, short, placeholder utterances that connote continued thinking (e.g., “*hmm*”, “*um*”, “*okay*”) were coded as Non-Instructional; however, “*okay*” was not automatically coded as Non-Instructional as it can also be an evaluation of a student’s response or serve another function, depending on its context.

Instructional statement type. Instructional Statements were further coded as Content-Specific, Generic, or Reading Aloud. Content-Specific Statements are statements about the content/disciplinary practices of the lesson and learning goals. For example, “*The mood of the play contributes to our understanding of the theme of the play.*” Generic statements are broad statements about organization, behaviors, materials, or checks for understanding connected to the lesson, as in “*Take out your journals, and turn to a new page.*” Reading Aloud statements

occur when the teacher or the students are reading aloud from a text verbatim. If the teacher is reading a short Instructional Statement or discussion question out of a textbook, off a PowerPoint slide, off a worksheet, etc., it is not considered Reading Aloud and is coded as Content-Specific. Furthermore, if the teacher stops reading to make a comment or interjects while the students are reading, those utterances are not coded as Reading Aloud. Similar to predictions made for Instructional Question Type, Generic and Clarifying codes were combined to predict Content-Specific Statements vs. Non-Content-Specific Statements.

2.1.3 Prevalence of discourse types

Our dataset contained a total of 24,755 teacher utterances, with 16,977 from the new Spring 2018 data and 7778 from CLASS5. Table 1 provides information about the prevalence of each of these types of discourse variables in this combined dataset.

Table 1: Summary of dataset

	Count	Proportion
Teacher	24755	
Question	7792	0.31
Instructional	7267	0.29
Content-Specific	5327	0.22
Non-Content-Specific	1940	0.08
Non-Instructional	525	0.02
Non-Question	16963	0.69
Instructional	12113	0.49
Content-Specific	8369	0.34
Non-Content-Specific	3744	0.15
Non-Instructional	4850	0.20

2.2 Machine learning

Using several modalities of features, we trained Random Forest classifiers implemented using the scikit-learn library [24] to perform a binary (present vs. absent) classification of these discourse features. We constructed models using three representations of the input data: as a set of engineered features computed from the audio and transcribed text of utterances, as a set of features derived via open-vocabulary language modeling, and finally as a combination of both of these sources.

We generated the set of engineered features using the acoustic, context, and linguistic features as described in [9]. Acoustic features were extracted from the audio of utterances using the OpenSmile toolkit [10], using the feature set from the 2009 Interspeech Emotion Challenge. This resulted in 384 acoustic features. Context features describe properties of the utterance such as its duration, its normalized (to unit variance) position in the overall classroom session, and the length of time of the surrounding pauses. In total, we considered 13 context features. Linguistic analyzers parsed the transcribed text and identified the presence of known question words and part of speech tags. These were found using the Brill Tagger [4] to identify certain question words, part-of-speech tags, and other keywords, resulting in 37 total features. The values of all these features were standardized to have a mean of 0 and unit variance. Standardization was computed using the formula $z = (x-u) / s$ such that z is the standardized score, x is the value of an individual sample, u the mean value of all training samples, and s is the standard deviation of the samples.

A bag-of-n-grams representation of input formed the open-vocabulary feature set. N-grams (of which we considered unigrams, bigrams, and trigrams) derived from the texts of

transcribed utterances were filtered according to the values of a few hyperparameters. We experimented using minimum document frequencies of 0.01, 0.02, and 0.03; PMI values of 0.2 and 0.4; and either including or excluding stopwords (see Section 1.1.2).

We implemented teacher-level 5-fold cross-validation to determine the best set of hyperparameters for models within each training fold. Specifically, we ensured that all utterances from the same teacher were always kept within the same train/test/validation fold. This helps ensure generalizability of our approach to new data and new teachers. To enable faster training of models, we limited the overall search space of hyperparameters, varying the parameters specified for the open-vocabulary models and leaving other parameters at default values as specified by scikit-learn. To overcome the underlying class imbalance in the dataset (see Table 1), we experimented using the imblearn library [18] to resample the minority class utterances such that both classes were more equally represented in the input dataset. This approach was applied to all models and only performed on the training set; class distributions in the validation and testing sets were unchanged.

3. RESULTS

We examined the ability of different types of models to predict five indicators of teacher discourse using utterances automatically segmented and transcribed by an ASR. We used area under the receiver operating characteristic curve (AUROC or AUC) as our primary outcome metric, which we computed using the pooled predicted probabilities from the five folds of our dataset. An AUC of 0.5 would signify chance performance.

3.1 Predictive language features

Table 2. Top 10 correlated n-grams

Variable	Top 10 correlated n-grams	Example sentences from dataset
Question	<i>does, did, think, good, say, mean, yes, guys, kind, make</i>	“why do you <i>say</i> you want to do”
Instructional Question	<i>does, did, think, good, say, yes, kind, mean, guys, make</i>	“are you <i>guys</i> doing”; “ <i>did</i> you talk to me on Friday”
Content-Specific Question	<i>does, think, did, good, kind, say, know, make, mean, people</i>	“okay why <i>does</i> she <i>think</i> it’s any better for her son”; “what <i>does</i> that <i>mean</i> ”
Instructional Statement	<i>na, gon, gon na, going, just, like, right, <hesitation>, look, little</i>	“all <i>right</i> now notice what you need to do <i>look</i> at this part”
Content-Specific Statement	<i>like, <hesitation>, going, na, just, gonna, gon, kind, little, right</i>	“ <i>like</i> if I’d done that all <i>right</i> I have a sample body paragraph here”

Note: <hesitation> expresses a token generated by ASRs to indicate hesitation in speech. Here we treat it as a word.

We analyzed our models to correlate the top 10 n-grams for each discourse variable in order to investigate characteristic language features. We calculated Spearman correlations of n-grams to the class labels (either 0 or 1) of the documents in which they appear.

These correlations were averaged across the five folds on which Random Forest models were trained. These n-grams are listed in Table 2, and we note some expected patterns. For example, one would expect that questions would be characterized by auxiliary verbs such as *does* and *did* as well as action verbs such as *think*, *say*, and *make*. We also observed considerable overlap between these categories. For example, both Instructional and Content-Specific questions include *does*, *think*, and *did* among their top three n-grams and share eight of ten most common n-grams. Likewise, Instructional and Content-Specific Statements share nine of the top ten most common n-grams. Conversely, we found that Content-Specific Statements and Questions have overlap only in the n-gram *kind*.

3.2 Comparison of feature sets

We constructed Random Forest models using three types of features: (1) engineered acoustic, context, and linguistic features, (2) bag-of-n-grams language features via open-vocabulary language modeling, and (3) a combination of both. Results using the Random Forest model are shown in Figure 1. We found that open-vocabulary language modeling resulted in the highest average AUC scores (average AUC = 0.74) for all discourse variables, followed by the combined set of features (average AUC = 0.72), while the engineered features were the least predictive (average AUC = 0.68). With respect to question detection, for which we have a baseline from previous work [9], we found that the current approach with language features yielded a 11% improvement over engineered features alone. These results demonstrate significant improvement (3-12%) over the previous state of the art.

Figure 1. Random Forest: AUROC per feature set

4. DISCUSSION

We investigated the extent to which several characteristics of classrooms discourse could be automatically identified at the utterance level. While prior work focused on predicting questions at the utterance level, in this study we detected several additional discourse characteristics at the utterance level, which would be of paramount importance in a real-time feedback system for teachers. We collected additional data from live classroom sessions during the Spring of 2018 to augment previously collected data. We developed a new coding scheme and manually annotated the dataset. Audio recordings of entire classroom sessions were automatically segmented into utterances which were then manually coded by humans and transcribed into text by the IBM Watson ASR. We then executed machine learning experiments to examine the extent to which these discourse variables could be recognized from the audio signal alone.

4.1 Main findings

First, we observed that open-vocabulary bag-of-n-grams Random Forest models outperformed our previous attempt using models built using only engineered features. These results demonstrate that the specific words a teacher uses, as determined by automatic transcriptions, may be of more utility than acoustic and prosodic cues, timing cues, rates of speech, parts-of-speech analysis, and closed-vocabulary word lists. Moreover, these findings indicate that the words most useful to differentiate between dialogic acts often differ from those anticipated by domain-specific closed-vocabulary lists. For example, closed-vocabulary lists created to predict questions may only look for whose words typically indicative of questions (e.g., *what*, *where*, *why*, *how*), while overlooking other words that may also be useful to distinguish this type of discourse (such as *think*, *say*, *mean*).

In summary, our results using open-vocabulary modeling (with AUCs ranging from 0.71 to 0.77) comfortably outperformed chance (AUC = 0.5), and reflect the state of the art performance on automatic modeling of classroom discourse. Further, the fact that the models were trained in a manner that generalizes to new teachers, and that the training data included audio from two different U.S. states across varying grade levels (mainly middle school for CLASS 5 vs. mainly high school for Spring 2018 data), increases our confidence in their generalizability. As such, we are optimistic that our present results reflect the feasibility of fully-automated utterance-level classrooms discourse modeling, a key step towards providing actionable feedback for teachers.

4.2 Limitations and future work

Although research indicates that the dialogic indicators of authenticity, uptake, and cognitive level are predictors of enhanced student engagement, this study does not aim to identify these indicators at the utterance level. This is because these variables have extremely low base rates (all under 10%), resulting in severe class imbalance when attempting to identify them from *all* teacher utterances. However, the automatic recognition of the discourse variables in this study serves as a precursor for subsequent approaches to better accurately identify these useful but infrequently occurring dialogic variables. The identification of these key dialogic variables relies on the ability to first correctly differentiate between more generic discourse properties, such as Questions vs. Statements, followed by Content-Specific Questions (of which Authentic Questions are a subset) vs. Instructional Questions.

In addition, we are currently limited by the lack of annotated data to provide sufficient exemplars of these specific dialogic properties (authenticity, uptake, and cognitive level) at the utterance level. Thus, additional collection of data would allow more examples of these more rarely occurring discourse types. Given this new data, we will extend our models to attempt to identify these infrequently occurring dialogic indicators.

Furthermore, continued improvement in the accuracy of our predictions is necessary to ensure the value of the assessment and feedback from our automated system. We plan on exploring several improvements to advance this goal. First, we will incorporate transcription metadata, such as the confidence values of the ASRs, in the models in order to weight individual words in the open-language model based on the quality of the transcription. Since words transcribed with a low confidence may be misidentified, excluding or discounting these words from language model may help to reduce modeling error. Second, we

will empirically experiment with varying the pause threshold used for segmentation. Perhaps a slightly longer or shorter gap in speech would provide a better separator of utterances. Third, we will continue to explore different supervised machine learning models or neural network architectures to further improve our ability to automatically identify these discourse indicators.

4.3 Concluding remarks

We hope that in our continued efforts towards automatic prediction of types of discourse, we can achieve the capability to provide valuable, actionable feedback to teachers about their instructional techniques so that they can better engage students in learning. Certainly, much work remains to be done in this area in order to improve upon our current ability. Nonetheless, this study forms an important step towards our overarching goal and serves as a foundation for future work in this area.

ABSTRACT

Peer assessment is a promising solution for scaling up the grading of a large number of submissions. The reliability of evaluations is one of the critical issues in peer assessment; several probabilistic models have been proposed for obtaining reliable grades from peers. *Peer correction* is a similar framework, in which students are instructed to correct the errors in submissions from other students. Peer correction is typically performed simultaneously with peer assessment; a reviewer is instructed to correct the errors in a submission and to provide a grade to it. We observe the occasional inconsistency between a grade and the correction; for example, a reviewer provides a high grade for a submission but she corrects many errors in it. Such inconsistencies can point to unreliable reviewers. In this paper, we propose probabilistic models for peer correction, and the combination of the peer correction models and the existing peer assessment models for capturing the inconsistency to accurately estimate the reviewer reliability and the student ability. We conduct experiments using the dataset of an actual peer correction platform for language translation, and the results demonstrate that the combination of peer correction models and peer assessment models improves the accuracy of the student ability estimation.

Keywords

Peer correction, peer assessment, statistical models

1. INTRODUCTION

MOOCs have changed education by offering open access to university course materials; however, not everything performed in offline classes is effectively introduced in MOOCs. An example is the ability assessment; in offline classes, teachers evaluate the student abilities by examining their submitted assignments and decide how to improve the educational efficiency. In contrast, assessing the abilities of tens of thousands of students in MOOCs is not feasible for teachers.

A promising solution for large-scale ability assessment is to allow students themselves to be involved in the evaluation; instead of teachers, students grade the submissions from other students. Such *peer assessment* approach is beneficial for scaling-up the ability assessment and it has been applied to several MOOCs courses [7]. However, the reliability of evaluations is one of the critical issues in peer assessment because some students may provide unreliable evaluations owing to laziness or lack of evaluation skills. Several probabilistic models have been proposed for estimating the reliabilities of the reviewers in order to accurately assess the student abilities in peer assessment [7, 4, 11, 8, 13, 6]. These models are based on the assumption that students with high ability are likely to provide reliable grades. The models are used to estimate the ability of a student as a test taker and the reliability as a reviewer.

In a similar framework of peer assessment, called *peer correction*, students correct the errors in the submissions from other students. Peer correction is helpful for teachers to reduce their efforts for providing feedback to the students. Typically, peer correction is performed simultaneously with peer assessment; a student is instructed to grade a submission and to correct its errors.

Although the outcomes of peer correction are naturally assumed to be informative for estimating the student abilities, probabilistic models for peer correction have not yet been investigated. Based on a natural assumption that a student who receives fewer corrections are likely to have a higher ability, we propose probabilistic models for peer correction that capture the relationship between the student abilities and the correction outcomes.

Additionally, we noticed an inconsistency between the outcomes of peer correction and those of peer assessment. In one case, a reviewer provides a high grade to a submission but she corrects many errors in it; in another case, a reviewer assigns a low grade but she does not make any corrections. Our idea is that such inconsistencies are beneficial in determining unreliable reviewers; thus, we propose to combine peer assessment models with our peer correction models. This combination allows us to capture the inconsistency and to incorporate it into the estimation of the reviewer reliability and the student ability.

We conduct experiments using a peer correction dataset about language translation. The results of the experiments

"Probabilistic Modeling of Peer Correction and Peer Assessment"
In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 426 - 431

show that our probabilistic models for peer correction are capable of estimating the student abilities, and the combined models of peer correction and peer assessment demonstrate a better performance in determining high-ability students than the peer assessment models.

The contributions of this paper are twofold: (i) we propose novel probabilistic models for peer correction that enable us to estimate the student abilities from the received corrections (Section 4), and (ii) we propose to combine our peer correction models and peer assessment models to exploit the inconsistencies among the outcomes of corrections and assessments (Section 6); the results of the experiments show that the combined models are efficient in accurately estimating the student abilities.

2. PROBLEM DEFINITION

We begin with the formulation of peer assessment and peer correction. We assume there is a set of students \mathcal{S} . When a student creates a submission for an assignment, other students (that we call *reviewers*) evaluate it and assign grades. The grade for the student $u \in \mathcal{S}$ assigned by the reviewer $v \in \mathcal{S}$ is denoted by $z_{uv} \in \mathbb{R}$. Each reviewer is additionally instructed to correct the errors in a submission. A correction result is denoted by y_{uv} . If a reviewer does not provide any correction for a submission, such information is also embedded in y_{uv} . The representation of y_{uv} is discussed in the next section.

Given a set of peer assessment and peer correction outcomes, \mathcal{D} , each of which is represented by a tuple (u, v, z_{uv}, y_{uv}) , our goal is to estimate the true abilities of the students $\{s_u\}_{u \in \mathcal{S}}$, where $s_u \in \mathbb{R}$.

3. DATASET

In this work, we use a peer assessment and peer correction dataset collected from Conyac¹, which is a crowdsourcing language translation platform. This platform employs peer correction and peer assessment between translators for collaboratively improving their skills; thus, a translator on this platform can be considered as a student. When a student submits a translation, other students evaluate its quality on a five-point scale (zero (low) to four (high)) and correct the errors in it. Students are invited to high-reward jobs if they have reviewed several submissions.

Students on Conyac can take a qualification test to demonstrate their skills. On this test, a student is instructed to translate the given sentences and then the translations are evaluated by experts employed by the service provider. According to the score, a student is assigned one of five expertise levels (D, C, B, A, and A+). This level is used for the job assignment and the default level is set to one. We consider the assigned levels as the ground truth of the student abilities, that we aim to estimate from the outcomes of peer assessment and peer correction.

We target the peer assessment and peer correction for Japanese to English translations on Conyac. Our dataset contains 5,008 reviews for 413 students, and 135 students

provide at least one review. Figure 1(a) shows the distribution of the grades assigned to translations and Figure 1(b) illustrates the distribution of the students' true expertise levels.

We conduct exploratory data analysis to investigate how the outcomes of peer correction can be used for estimating student expertise levels. A natural expectation is that a student whose submissions are likely to be corrected would have lower ability. We calculate the correction ratio of each student, which is the number of corrected submissions divided by the number of submissions. Figure 1(c) shows the average correction ratio of the students in each expertise level. We observe that students with the highest level are likely to have lower correction ratios than the others.

Additionally, we consider that students who have more errors in their submissions would be have lower ability. We calculate the number of corrected parts in each submission by applying the Gestalt pattern matching [10]. We first obtain the matched patterns in pre-correction and post-correction submissions, and then count the number of unmatched patterns in the post-correction submissions. The examples of the calculated numbers are shown in Table 1 and Figure 1(d) shows the distribution of the number of corrected parts in each submission. We calculated the average number of corrected parts of each student and Figure 1(e) presents the average of the values at each level. We found that the students with higher levels are likely to have a lower number of corrected parts.

From these observations, we decide to use the following binary and numerical variables to represent a correction outcome: (1) $y_{uv}^{(b)} \in \{0, 1\}$, which indicates whether the corresponding submission is corrected by the grader ($y_{uv}^{(b)} = 0$) or not ($y_{uv}^{(b)} = 1$), (2) $y_{uv}^{(n)} \in \{0, 1, 2, \dots\}$, which indicates the number of parts corrected by the grader.

4. PEER CORRECTION MODELS

We propose two peer correction models, PC_b and PC_n , for estimating the student true abilities. The models are illustrated in Figure 2(a).

4.1 PC_b model

We first present a generative model for $y_{uv}^{(b)} \in \{0, 1\}$, which is a binary indicator whether the submission has been corrected by the reviewer or not. We have two latent parameters into our model, that is, student true ability and reviewer bias; each student is associated with the latent true ability, $s_u \in \mathbb{R}$, which we aim to estimate, and each reviewer has a different bias parameter, $b_v \in \mathbb{R}$, presuming that a reviewer with a lower bias tends to review a submission negatively.

Following the observations, we assume that a submission from a student is likely to be not corrected by a reviewer if the student has high ability. In addition, a reviewer is not likely to correct a submission if he/she has a higher bias. These assumptions are represented as the following generative model:

$$y_{uv}^{(b)} \sim \text{Bern}\left(y_{uv}^{(b)} \mid \sigma(s_u + b_v + r)\right), \quad (1)$$

where $\sigma(x) = 1 / (1 + \exp(-x))$, $\text{Bern}(\cdot)$ is the Bernoulli dis-

tribution, and r is a noise. Note that $y_{uv}^{(b)} = 1$ indicates that the corresponding submission is *not* corrected by the reviewer. We denote this generative model by PC_b model. We can interpret $s_u + b_v + r$ as an apparent ability of the student u for the reviewer v at the time. The model indicates that a submission is likely to be not corrected when the apparent ability is high.

In the same way as the existing peer assessment models that will be reviewed in the next section, we use normal distributions as priors for s_u , b_v , and r :

$$\text{(Student ability)} \quad s_u \sim \mathcal{N}(s_u | \mu_0, 1/\gamma_0) \quad (2)$$

$$\text{(Reviewer bias)} \quad b_v \sim \mathcal{N}(b_v | 0, 1/\eta_0) \quad (3)$$

$$\text{(Noise)} \quad r \sim \mathcal{N}(r | 0, 1/\kappa_0), \quad (4)$$

where μ_0 , γ_0 , η_0 , and κ_0 are hyperparameters.

4.2 PC_n model

Our second model targets the number of corrected parts in each correction, $y_{uv}^{(n)} \in \{0, 1, 2, \dots\}$. Following the observations from the actual dataset, we assume that a reviewer corrects more parts of a submission when the student has a lower ability. We use the Poisson distribution to represent this assumption:

$$y_{uv}^{(n)} \sim \text{Poisson} \left(y_{uv}^{(n)} \middle| \frac{1}{\exp(s_u + b_v + r)} \right).$$

Similar to the PC_b model, $s_u + b_v + r$ is considered as the apparent ability of the student u to the reviewer v , and this model indicates that more parts of the submission is likely to be corrected by the reviewer if the apparent ability of the student is lower. We call this model PC_n . The priors given in Eqs. (2), (3), and (4) are incorporated into the PC_n model as well.

Figure 2: Peer correction and peer assessment models, and combined models

5. PEER ASSESSMENT MODELS

We next review the existing peer assessment models, which are combined with our peer correction models in the next section. In particular, we summarize the PG₁ [7], PG₃ [7], PG₄ [6], and PG₅ [6] models². These are the generative models for grades, $z_{uv} \in \mathbb{R}$. The peer assessment models are illustrated in Figures 2(b) and 2(c).

The student ability and the reviewer bias parameters are also incorporated in the peer assessment models. All the models use the same priors given in Eqs. (2) and (3).

5.1 PG₁ and PG₃ models

In addition to the latent parameters incorporated in the peer correction models (s_u and b_v), the peer assessment models contain the reviewer reliability $\tau_v \in \mathbb{R}^+$. This parameter indicates how likely a grade given by the reviewer contains a noise. PG₁ is defined as follows:

$$\begin{aligned} \text{(Reviewer reliability)} \quad \tau_v &\sim \text{Gamma}(\tau_v | \alpha_0, \beta_0) \\ \text{(Outcome)} \quad z_{uv} &\sim \mathcal{N}(z_{uv} | s_u + b_v, 1/\tau_v), \end{aligned}$$

where α_0 and β_0 are hyper parameters. PG₃ is an extension of PG₁, which incorporates the relationship between the reviewer reliability and the ability of the reviewer (as a student). PG₃ is given as follows:

$$\begin{aligned} \text{(Reviewer reliability)} \quad \tau_v &= \theta_1 s_v + \theta_0 \\ \text{(Outcome)} \quad z_{uv} &\sim \mathcal{N}(z_{uv} | s_u + b_v, 1/\tau_v), \end{aligned}$$

where θ_0 and θ_1 are hyperparameters.

5.2 PG₄ and PG₅ models

PG₄ and PG₅ are variations of PG₃ and they incorporate the relationship between the reviewer reliability and the reviewer ability into the priors of the reliability parameter. The generative models of the reviewer reliability and outcome in PG₄ are given as follows:

$$\begin{aligned} \text{(Reviewer reliability)} \quad \tau_v &\sim \text{Gamma}(\tau_v | s_v, \beta_0) \\ \text{(Outcome)} \quad z_{uv} &\sim \mathcal{N}(z_{uv} | s_u + b_v, 1/\tau_v), \end{aligned}$$

and those in PG₅ are given as follows:

$$\begin{aligned} \text{(Reviewer reliability)} \quad \tau_v &\sim \mathcal{N}(\tau_v | s_v, 1/\beta_0) \\ \text{(Outcome)} \quad z_{uv} &\sim \mathcal{N}(z_{uv} | s_u + b_v, \lambda/\tau_v), \end{aligned}$$

where β_0 and λ are hyperparameters.

²We do not include PG₂ [7], which is almost similar to PG₁ except it incorporates time-series factors.

6. COMBINED MODELS FOR PEER CORRECTION AND PEER ASSESSMENT

We finally combine our peer correction models and the existing peer assessment models. By combining these two types of models, we expect to capture an inconsistency between the outcome of peer correction and that of peer assessment; the inconsistency can be informative for estimating the reviewer reliabilities.

We use PG₁ and PC_b to explain the model combining and we term the combined model as PG₁+PC_b. We simply consider that s_u and b_v are shared between these two models; namely, the generative model for PG₁+PC_b is given as:

$$\begin{aligned} \text{(Student ability)} \quad s_u &\sim \mathcal{N}(s_u | \mu_0, 1/\gamma_0) \\ \text{(Reviewer reliability)} \quad \tau_v &\sim \text{Gamma}(\tau_v | \alpha_0, \beta_0) \\ \text{(Reviewer bias)} \quad b_v &\sim \mathcal{N}(b_v | 0, 1/\eta_0) \\ \text{(Noise)} \quad r &\sim \mathcal{N}(r | 0, 1/\kappa_0) \\ \text{(Outcomes)} \quad z_{uv} &\sim \mathcal{N}(z_{uv} | s_u + b_v, 1/\tau_v), \text{ and} \\ y_{uv}^{(b)} &\sim \text{Bern}(y_{uv}^{(b)} | \sigma(s_u + b_v + r)). \end{aligned}$$

The PG₁+PC_b model is illustrated in Figure 2(d). Other combined models are defined similarly as PG₁+PC_b.

When an inconsistency occurs between corrections and grades, i.e., a reviewer provides a high grade to a submission but makes many corrections in it, we consider that a large noise occurs on the grade (z_{uv}) and thus the reliability of the reviewer (τ_v) is estimated as low. The combination of peer assessment models and peer correction models allows us to leverage such inconsistencies to estimate the reviewer reliabilities and the student abilities.

7. EXPERIMENTS

We conduct experiments using the actual peer assessment and peer correction dataset about language translation. We investigate the effectiveness of the proposed methods to estimate the student abilities.

7.1 Baselines

We compare the proposed models (PC_b, PC_n, and PG_{1,3,4,5}+PC_{b,n}) with the following baselines: **(a) Correction ratio (PC_b[#])**: this is a naïve version of PC_b and considers the correction ratio of each student as the ability. Specifically, the correction ratio is defined as $-\sum_{y_{uv}^{(b)} \in \mathcal{Y}_u^{(b)}} \delta(y_{uv}^{(b)} = 0) / |\mathcal{Y}_u^{(b)}|$, where $\mathcal{Y}_u^{(b)}$ is the set of correction outcomes for the student u , and $\delta(\cdot)$ is the in-

Table 2: Average and standard deviation of AUC scores of each method on various classification boundaries. Each column indicates the results for each classification boundary; for example, (D, C, B, A | A+) represents the results for classifying the students at A+ and the others. The winner for each boundary is bold-faced. The cases where a combined model outperforms the corresponding peer assessment model (PG₁, PG₃, PG₄, or PG₅) are underlined.

	AUC			
	(D, C, B, A A+)	(D, C, B A, A+)	(D, C B, A, A+)	(D C, B, A, A+)

indicator function. For assigning a higher ability for a student with less corrections, we multiply the value with -1 . **(b) Mean number of corrected parts (PC_n[#]):** this is a naïve version of PC_n and considers the mean number of the corrected parts of each student as the ability. Specifically, the mean number of the corrected parts of the student u is defined as $-\sum_{y_{uv}^{(n)} \in \mathcal{Y}_u^{(n)}} y_{uv}^{(n)} / |\mathcal{Y}_u^{(n)}|$, where $\mathcal{Y}_u^{(n)}$ is the set of correction outcomes for the student u . For assigning a higher ability for a student with less corrected parts, we multiply with -1 . **(c) Mean grades (PG[#]):** this is a naïve version of PG₁ and considers the mean assigned grades of each student as the ability. The mean grade is defined as $\sum_{z_{uv} \in \mathcal{Z}_u} z_{uv} / |\mathcal{Z}_u|$, where \mathcal{Z}_u is the set of grades assigned to the student u . **(d) PG₁, PG₃, PG₄, and PG₅:** existing peer assessment models.

7.2 Experimental setup

We implemented the models using the No-U-Turn Sampler (NUTS) [3], which is a variation of the Hamiltonian Monte Carlo. We executed four chains and they produce 5,000 samples in total. The initial 500 samples were ignored and the average of the rest samples were used as the estimated parameters.

We randomly generated 150 sets of candidate hyperparameters for each method. A method with a set of candidate hyperparameters produces the estimated student abilities. Their performance was evaluated using the groundtruth of 20% of the students. We then decided the best set of hyperparameters for the method and the final result for each method was evaluated by the remaining students. We performed this procedure five times and calculated the average.

Each method outputs the estimated ability of each student. We use the expertise levels assessed by the experts as the ground truth, and investigate how accurately each method

classifies the students with high expertise and those with low expertise. We specifically use the area under the ROC curve (AUC) as an evaluation metric.

7.3 Results

Table 2 shows the AUC scores of each method on different classification boundaries. Our peer correction models (PC_b and PC_n) demonstrate better or comparative performance to the existing peer grading models in detecting the students at the highest level; this supports the effectiveness of the peer correction results for estimating student abilities. We see that the “no-correction” cases only occur for high-ability students and the correction information is helpful for distinguishing between the “perfect students” and “almost perfect students”, both are likely to obtain the highest grades from the reviewers and the correction outcomes are required to classify them.

In contrast, the performance of peer correction models becomes inferior for detecting the students at lower levels, and PG[#] achieves the best performance for detecting the students at the lowest level; the average of the obtained grades is sufficiently informative for detecting low-ability students. Our methods would be beneficial for a situation where teachers aim to detect students who require advanced course materials or assignments.

The combined models of PG_{1,3,4,5}+PC_b outperform the corresponding PG_{1,3,4,5} in most cases; the outcomes of peer correction are useful for improving the student ability estimation. It is noteworthy that PG₅+PC_b achieves an AUC of 0.914 for classifying the students at A+ and the others. This result is brought by the capability of the combined models for capturing the inconsistencies between the outcomes of assessments and those of corrections.

The number of corrected parts can be more informative than simply considering whether a submission is corrected; in fact, PC_n is better than PC_b and PC_n^\sharp performs better than PC_b^\sharp ; however, $PG_{\{1,3,4,5\}} + PC_b$ outperforms $PG_{\{1,3,4,5\}} + PC_n$ in our experiments. Because there are more model variations in PC_n than PC_b , a more meticulous modeling for combining the PG models and the PC_n model would be required.

8. RELATED WORK

Peer assessment models are categorized into two groups: models for cardinal peer assessment and models for ordinal peer assessment. The former models target a situation where the outcomes are assigned in explicit numerical scores, such as five-point scores. In addition to the probabilistic models reviewed in Section 5, Walsh proposed PeerRank [13], an extension of PageRank for peer assessment. In ordinal peer assessment, each grader is shown multiple submissions and instructed to rank them. The Bradley–Terry model [2] has been applied for ordinal peer assessment [11, 8] and Mi et al. proposed to use the cardinal peer assessment models for ordinal peer assessment [6]. Although several probabilistic models for peer assessment have been studied, peer correction has not yet been investigated.

The design of peer assessment frameworks has been attempted to improve the reliability of evaluation. Kulkarni et al. ([4]) reported that the feedback about the grading bias to graders was beneficial for improving the reliability. Another work proposed to design peer assessment as a multiple choice task where a grader is instructed to choose the best submission [5]. Peer assessment mechanisms based on game theory have been introduced to derive accurate evaluations from peers [14].

Our peer correction models are very related to the models studied in the item response theory, which are for quantifying student abilities and item characteristics in educational tests. One of the simple item response theory model is the Rasch model [9] and our PC_b (given in Eq.(1)) model has a similar formulation to the Rasch model.

Besides peer assessment, probabilistic models for estimating grader reliability have been studied in crowdsourcing as well. Specifically, a two-stage framework was proposed where crowdsourcing workers in the first stage produce outputs, such as translations or logo designs, and another set of workers in the second stage evaluates the outputs [1]. Probabilistic models for estimating the reliability of each grader and the quality of each output in this two-stage framework have been proposed [1, 12]. Unlike peer assessment, the overlap between students (i.e., creators of outputs) and graders is not assumed in crowdsourcing.

9. CONCLUSIONS

We presented probabilistic models for peer correction, which are used for estimating the student abilities. We proposed two models: one considering whether a grader has corrected a submission, and the other utilizing the number of corrected parts in each submission. We also combined the peer correction models with the peer assessment models; this combination allows us to estimate the reliability of graders from the outcomes of peer corrections and those of peer assess-

ment by considering the consistency between the corrections and assessments. The experiments using the actual dataset of peer correction showed that the combination of peer correction models and peer assessment models was particularly effective in detecting high ability students.

In our models, we did not consider the importance of each corrected part; however, the importance levels differ among corrected parts in which minor corrections (e.g., adding a punctuation mark) and major corrections (e.g., paraphrasing) exist. A major correction would indicate the low quality of a submission and considering such factors is a promising direction to improve the ability estimation accuracy.

ABSTRACT

Understanding the affect expressed by learners is essential for enriching the learning experience in Massive Open Online Courses (MOOCs). However, online learning environments, especially MOOCs, pose several challenges in understanding the different types of affect experienced by a learner. In this paper, we define two categories of emotions, *explicit* emotions as those collected directly from the student through self-reported surveys, and *implicit* emotions as those inferred unobtrusively during the learning process. We also introduce positivity as a measure to study the valence reported by students chronologically, and use it to derive insights into their emotion patterns and their association with learning outcomes. We show that implicit and explicit emotions expressed by students within the context of a MOOC are independent of each other, however, they correlate better with students' behavior compared to their valence.

Keywords

MOOC, emotions, discussion forum, valence, surveys

1. INTRODUCTION

The exploration of emotions expressed by students in Massive Open Online Courses (MOOCs) has caught the attention of researchers for improving the remote and non-contact learning experience [28, 8, 16, 5]. A few examples of these studies infer emotions of students from their behavior [16], surveys collected during the course [8, 1], clickstream data and discussion forums [28, 5]. The relationship between students' emotions and their behavior, learning outcomes, engagement, and dropout within the MOOC context is established in [1, 25, 21].

Emotions experienced by students during a course impact their behavior and learning outcomes [15, 19]. Detecting the emotion experienced during learning is difficult, and various methods have been employed for this purpose. The methods used to sample emotions mainly fall into three categories

as outlined by [27]. The first category consists of methods that take snapshots of students' emotions during the course through survey questionnaires. These methods are intrusive to the learning process and are usually self-reported and subjective in nature. The second category detects emotions during the learning process and includes methods that sample emotions non-intrusively like facial expression detection, conversations, gaze detection, and analysis of text data generated by student interactions within the course [9, 10]. The third category measures emotions after the learning process. The first two categories are relevant to our paper. In [27], the methods in the second category are assumed to counteract the limitations of the methods in the first category. Therefore, in our study we use two categories of emotions to get a more complete view of students' emotional states. In this paper, we measure explicit emotions as the emotions recorded from student's self-reported surveys and Self-Assessment Manikins (SAMs), and implicit emotions as those from the open discussion forum posts of students.

Emotions measured in association with learning seem to be short-lived and last for a few seconds to minutes [15]. Since the emotions were expressed by students in this MOOC at different, non-uniform points in time, one of the challenges of analyzing such a series is the spontaneity of emotions. As the emotions are surveyed after the end of a video or module, we only get a snapshot of the students' emotions during the course [27]. Between two consecutive surveys, a student's emotions can not only change multiple times, but also be conflicting, as students can experience multiple emotions simultaneously [1], which could hinder a chronological analysis of the emotions. However, even if students' emotions are spontaneous and likely to be fraught with missing data, there might be a trend to their emotions over time. An approach that leverages this idea has been proposed in [7], where the positive affect experienced by an individual is averaged over a period of time while the negative reports are ignored. Inspired by this technique, we also calculate the "positivity" of students at each point of the reported emotions and derive a positivity sequence instead of an emotion sequence. This positivity sequence is expected to be more stable over time as compared to the emotion sequence.

We study the implicit and explicit emotions expressed by the MOOC students through the following research questions.

RQ1: Are the explicit and implicit emotions expressed within a MOOC context similar? Can one be used as a proxy for

Munira Syed, Malolan Chetlur, Shazia Afzal, G. Alex Ambrose and Nitesh V. Chawla "Implicit and Explicit Emotions in MOOCs" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 432 - 437

the other or are both of them equally important for characterizing a student's emotional state?

RQ2: What do the combined (explicit plus implicit) emotional states and positivity sequences characterize about a student's learning?

To the best of our knowledge, this is the first attempt at investigating the effect of explicit and implicit emotion categories within a MOOC context. We find that implicit and explicit emotions expressed by students are indeed different and both are necessary to characterize student emotions. We also see that combined positivity values correlate relatively well with behavior compared to their valence values.

2. RELATED WORK

The comparison of self-reported metrics like emotions and performance in self-regulated learning and other educational contexts has been studied and generally found to be inconsistent with the measured reports [14, 26, 29]. While many of these studies measure the alignment of students' achievement calibration with their actual performance [13, 26, 14], we aim to compare the self-reported emotions of students in MOOCs against the emotions we measure from their behavior in the MOOC, in the form of interactions on the discussion forum. A direct comparison of these methods with ours is infeasible because of the difference in instrumentation and methodology. However, we will compare our general observations with the trends in literature.

We use students' self-reports of emotions along with Self-Assessment Manikin (SAM) as the explicit measures of students' emotions. Self-reports are a very common way of measuring students' emotions because of their subjective nature [11]. Collecting students' emotions through surveys is easy to deploy on a large-scale and is low cost [11], which makes them favourable for use in MOOCs [1]. SAM is a non-verbal assessment technique that allows people to rate their pleasure, represented as valence in our case, on an ordinal scale [4]. SAMs have been used to measure emotion in online learning environments [6, 8].

Among the techniques available for detecting the implicitly expressed emotions of students, analyzing emotions from texts is one of the least invasive ways of detecting students' emotions [17, 22]. Using discussion forums to detect students' emotions in MOOCs is becoming prominent due to its unobtrusiveness and low instrumentation [28]. Many sentiment analysis techniques for detecting valence from text including the word-affect lexicon used in this paper are listed in [18], and education has been noted as one of the applications of sentiment analysis. We use Warriner's [24] word-affect lexicon to calculate the valence values of words in the discussion forum records. The effectiveness of Warriner's word-affect lexicon [24] for sentiment analysis has been demonstrated for detecting sarcasm [20], finding geographical locations associated with happier tweets [12], etc. This automatic method to detect affect from discussion forum data enables a scalable way to glean implicit affect in MOOCs from a large number of forum posts. Sentiment analysis polarity techniques were applied on discussion forum posts in [25]. In [28], a Mechanical Turk is used to obtain confusion ratings among students through simple features like counting the number of question marks to predict

**Table 1: 1. Number of students vs. SAM surveys
2. Number of students vs. SAM scores**

SAM survey	No. of students	SAM score	No. of students
1	4111	1	3204
2	2815	2	4355
3	1354	3	1557
4	906	4	295
5	326	5	101

the level of confusion in the discussion forum posts. They also use Linguistic Inquiry and Word Count (LIWC) to consider negation words and phrases as an indicator of potential confusion, and clickstream patterns (eg. quiz-quiz-forum) as a feature for detecting confusion. Previous research on using the discussion forum to estimate student retention and performance is complicated due to a vast amount of missing and imbalanced data [3]. We also face challenges to detect implicit emotions in the midst of context-specific terms.

3. DATA DESCRIPTION

3.1 Course Description

We use the data from the introductory course on Statistics called "I Heart Stats" for our study. This was a self-paced MOOC on the EdX platform, and the entire course content was released at the start of the course. The course had nine modules, with the ninth module being for the assessment of the overall course. During the course, students were asked to self-report their emotions and valence through emotion surveys and SAM surveys respectively. Initially 24,279 students were enrolled in the course, however, only less than 15,000 students had activity in the first two weeks. Finally, only 1,941 students completed it. Of all the students, 1,629 responded to at least one emotion or SAM survey, and participated in the discussion forum as well. Only these students have been included in the Analysis section of the paper as these are the only students generating both implicit as well as explicit emotions. Note that students completing the course are likely to have longer sequence lengths. Students not interacting with the discussion forum but are still part of the course cannot be included in the analysis leading to an overrepresentation of active users.

3.2 Explicit Emotions

Emotion Surveys: Of all the students, 6,100 submitted 21,448 emotion surveys. During the course, 12 emotion surveys were conducted in which students self-reported their current emotional state. This was optional and students could choose multiple of a list of 15 emotions: *anger, anxiety, boredom, confusion, contentment, disappointment, enjoyment, frustration, hope, hopelessness, isolation, pride, relief, sadness, and shame*. Further details can be found in [1]. The valence values of these emotions were calculated using Warriner's lexicon [24], with a scale of 1 to 9 and 5 being neutral. We shift the scale to $[-4, 4]$ to bring the neutral valence to 0. In the case of multiple emotions being expressed, the associated valence values were averaged to obtain one valence value per survey. Thus, the surveys have positive $(0, 4]$, negative $[-4, 0)$, and neutral $\{0\}$ valence values.

Figure 1: Histogram of implicit, explicit, and combined sequence lengths (until sequence length of 25)

SAM Surveys: A total of 5 SAM surveys, using a 5-point scale, were conducted in this MOOC. The SAM score represented in Table 1 ranges from 1 to 5 with 1 being the least and 5 being the highest state of pleasure. As the distribution of the number of students corresponding to each SAM score is normal, we convert this scale to an interval scale in the range $[-4, 4]$ linearly. In total, 5,363 students have submitted 9,512 SAM surveys with the rest of the details shows in Table 1.

3.3 Implicit Emotions

The discussion forum is a platform that students use to interact with each other, the instructor, and teaching assistant of the MOOC. In total, 1,717 students generated 5,322 discussion forum records. The posts, comments, and replies (i.e. records) on the discussion forum are used to infer the implicit emotions of students.

We use Warriner’s word-affect lexicon [24] to calculate the valence values of discussion form records. The tokenized words in tweets are used to calculate the mean valence value of the tweet using Warriner’s word-affect lexicon. We use a similar approach to calculate valence values for discussion forum records using the following steps: (i) Tokenize the records to get a list of words, (ii) Remove the stop words from the list, (iii) Make a list v of valence values associated with a word using the lexicon, if present, after re-scaling them between $[-4, 4]$, (iv) Multiply the valence values of words/phrases that follow a negative word with -1 (eg. not, never), and (iv) Return the average valence value of list v .

3.4 Combined Emotions

Throughout the course, students have multiple opportunities, explicit or implicit, to express their emotions. The 12 emotion surveys, 5 SAM surveys, and valence values calculated from discussion forum records were interleaved and ordered chronologically for each student to form a combined sequence of valence values.

A histogram of the number of reports corresponding to the number of students in Figure 3.4 shows that the highest number of students (14%) has a maximum combined sequence length of 3 with the number of students tapering

down after that point. The maximum number of reports corresponding to a student is 74, as this student was very active in the discussion forum.

To mitigate the spontaneous nature of emotions, we calculate the positivity of students at each report from the valence sequence values. Thus, if a student reports one negative emotion among a string of positive emotions, the impact of the negative emotion is reduced because of the previously expressed positive emotions. We define positivity as follows.

Positivity: Let r_1, r_2, \dots, r_n be the reports made by a student until element n such that: $timestamp(r_{i-1}) < timestamp(r_i)$ for all i . The valences are normalized between $[-1, 1]$, instead of $[-4, 4]$, by dividing them by 4. Let p_1, p_2, \dots, p_m be the positive normalized valences where $m \leq n$ and $m + 1 > n$. The positivity at the n th element is given by $(p_1 + p_2 + \dots + p_m)/n$.

In other words, an element of the positivity sequence is calculated by averaging over only the positive valences in the sequence until that element. Since students have reported more positive than negative valences both explicitly and implicitly, calculating negativity instead of positivity would lead to extremely sparse sequences.

4. ANALYSIS

4.1 Calculated Valences

Section 3.3 lists the steps to calculate the valence values of the discussion forum records. To validate these valence values, 440 samples of the discussion forum records were manually annotated by three human raters in which each rater chooses one, two, or none of the 15 emotion choices that students had for their emotion surveys. The fourth rater is the calculated valence. We use Fleiss’ Kappa [2] to calculate the inter-rater agreement by converting the valence scores to positive, negative, or zero valence. The inter-rater agreement of the three human raters is 0.457 (moderate agreement), whereas the inter-rater agreement of the four raters including the calculated valences is 0.218 (fair agreement) [23]. While the agreement including the calculated valences is lower, it is adequate, and so we use the calculated valence of these discussion forum records as the implicit valence values.

4.2 Implicit vs. Explicit features (RQ1)

Both implicit and explicit sequences are instances of irregular time-series data. However, since emotion data is spontaneous and might change multiple times between consecutive reports [15], averaging, downsampling, interpolating or duplicating valence values in an emotion sequence might misrepresent the true emotional trajectory of the student.

4.2.1 Feature vectors description

Since the valence sequences are not uniform in length, we create fixed length feature vectors for analysis. The features are used in Sections 4.2.2 and 4.2.3 with their description given: (i) *pos*: ratio of the number of positive valences to the total length of the sequence (ii) *neg*: ratio of the number of negative valences to the total length of the sequence (iii) *neu*: ratio of the number of neutral valences to the total length of the sequence (iv) *trans*: ratio of the number

Table 2: Corr. between implicit & explicit features

Features	Pearson's r	Spearman's rho
pos	0.0401	0.0696**
neg	0.0413*	0.102***
neu	0.0150	0.0380
seq_len	0.346***	0.422***
trans	0.125***	0.162***
neg_pos	0.113***	0.165***
pos_neg	0.0805**	0.127***
range	0.243***	0.257***

*:p-val.<0.1, **:p-val.<0.05, ***:p-val.<0.0001

of transition of valences from positive to negative or vice versa in the sequence to the sequence length (v) *pos_neg*: ratio of the number of transition of valences from positive to negative to the sequence length (vi) *neg_pos*: ratio of the number of transition of valences from negative to positive to the sequence length (vii) *range*: calculated by subtracting the minimum valence value from the maximum valence value expressed (To normalize the value the resulting range is divided by 8, as the valence values lie in the range [-4, 4].) (viii) *seq_len*: length of the valence sequence (integral value).

4.2.2 Correlation

In Table 2, we see that *pos*, *neg*, and *neu*, as defined in Section 4.2.1, between implicit and explicit emotions of students are not correlated with each other. This shows that both types of sequences are somewhat independent of each other and might show different insights into students' affect. There are relatively few neutral discussion forum records which is why its correlation with completion is not significant. That is why transitions from neutral to positive and negative valences, and vice-versa have been left out of the features list. The sequence lengths seem to be mildly correlated showing that students reporting more emotions in the emotion surveys were also more likely to submit more records in the discussion forum. This correlation is expected since the number of students with larger sequence lengths decreases as seen from Figure 3.4.

4.2.3 Clustering of Feature Vectors

We cluster the 7-dimensional feature vector to identify groups of similar students using K-Means. To visualize the clusters created, we decompose the 7-dimensional feature vectors of students' implicit and explicit emotion sequences to a 2-dimensional space using Principal Component Analysis (PCA) separately. The PCA decomposition in Figure 4.2.3 shows very separable clusters in the 2-dimensional space. The explicit clusters have significantly different ratios of course completion: orange: 37.2%, purple: 25.5%, olive: 51.9%. Similarly, the completion ratios of the implicit clusters are: red: 34.5%, blue 32.6%, green: 60.3%, with the green cluster having significantly more students completing the course than the other two.

4.3 Combined sequence features (RQ2)

From the previous subsection, we saw that implicit and explicit sequences are not identical and should both be incorporated into a student's valence trajectory. So we use both

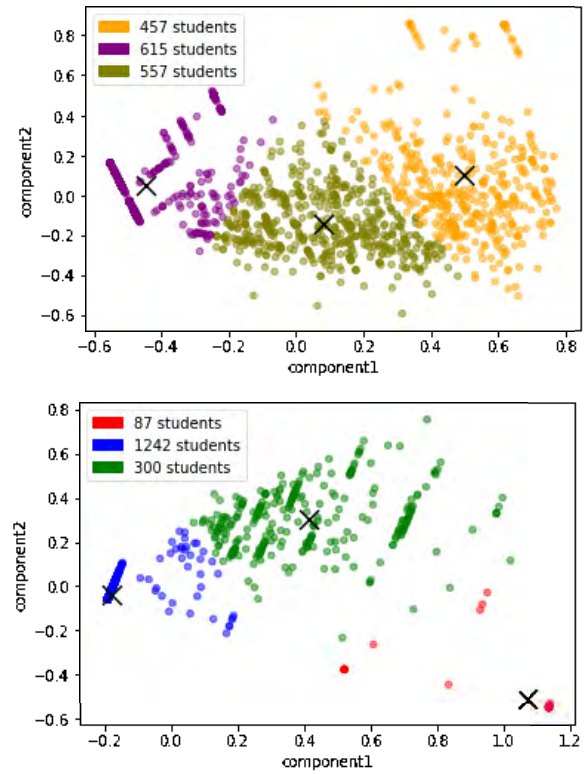

Figure 2: PCA decomposition of explicit (top) and implicit (bottom) seq. clusters ('x': cluster centers)

implicit and explicit sources of emotions ordered by time to generate a combined valence sequence for students. The features from Section 4.2.1 are used in the analysis below.

4.3.1 Correlation of features with completion

We generate the 7-dimensional feature vector from the combined valence sequence for each as defined in Section 4.2.1 and show the correlation of each dimension with completion in Table 3. Completion is defined by a student reaching module 8 [1]. We see that *seq_len* has the highest correlation with completion possibly because sequence length could act as proxy for the amount of time students spent in the course. A similar reasoning might hold for *trans*. The *pos*, *neg*, or *neu* features do not seem to be correlated with completion. However, *neg_pos* seems to be better correlated with

Table 3: Corr. of combined vectors with completion

Feature	Pearson's r	Spearman's rho
pos	-0.0549***	-0.110***
neg	0.0807***	0.156***
neu	-0.0382**	0.0828***
neg_pos	0.215***	0.300***
pos_neg	0.112***	0.201***
trans	0.186***	0.223***
seq_len	0.523***	0.460***
range	0.390***	0.392***

: p-val. <0.05, *: p-val. <0.0001

Table 4: Corr. of features with quiz performance

Features	average	minimum	maximum
range	-0.0804*	-0.181***	0.0735*
seq_len	-0.232***	0.0681*	-0.405***

*: p-val.<0.1, **: p-val.<0.05, ***: p-val.<0.0001

Figure 3: Positivity Clustering of Combined Seqs.

completion than *pos_neg*. This supports our intuition that students transitioning from a negative to positive emotional state are more likely to stay in the course, compared to the other way round. The feature *range* is better correlated with completion than *trans* which indicates that higher intensity of changes in emotions is more likely to result in completion.

4.3.2 Correlation of features with Quiz Performance

The performance score of students for a quiz is normalized between 0 and 1. The average, minimum, and maximum performance score of the quizzes (total 4) that students have attempted is used as the y-variable for correlation. The features that are significantly correlated with these statistics using Pearson’s correlation are in Table 4. While the negative correlation with *seq_len* is unsurprising given that harder quizzes are towards the end of the course, the positive correlation with *range* suggests that student who experience extreme emotions tend to perform better.

4.4 Positivity clustering (RQ2)

We compare fixed length positivity sequences by clustering the first 10 elements of 767 students who have a sequence length of at least 10. We see that $k=3$ is the highest number that shows no overlap of cluster centers. While there is no significant difference between the clusters for quiz performance, the difference between clusters in terms of quiz participation using ANOVA is significant at $p\text{-value} < 0.05$. Specifically, in the $k=3$ chart in Figure 4.4, there are more students in the most positive (green) cluster that do not submit a single quiz (29.3%) than the other two clusters (20%). A possible explanation is that students had trouble with the quizzes and the ones who did not attempt them were more likely to be happier. All three cluster centers converge to-

wards a narrow range of positivity, suggesting that students tend towards the same positivity in the course even though they started out differently.

5. DISCUSSION AND FUTURE WORK

Similar to the studies [14, 26, 29], we found that the self-reported emotions did not reflect the implicitly measured emotions. Clustering students by their emotion sequence had different ratios of students that completed the course in each cluster. This observation is similar to what [14] found about different learning strategies and activity of students. To investigate whether the temporally proximal self-report was correlated with the outcome completion, we measured the correlation of the last reported valence and the final positivity in the students’ sequences with completion. However, similar to [29], we found no correlation. This suggests that the proximity of students’ emotions to the outcome completion does not have a bearing on completion.

Through RQ1, we show that both the implicit and explicit emotion sequences are independent of each other and contribute different emotional information. Through RQ2, we showed that students tend to converge towards the same positivity even though they start out differently, indicating that they end up feeling the same way. This might be because of external factors that remained constant for all the students, e.g., how the course was conducted, possibly explaining the lack of correlation with the course outcomes. We see significant differences between these clusters in quiz participation but not in other learning outcomes. This may be because students who did not attempt the quizzes did not struggle through the course and remained relatively happy. Our results show that there is potential for identifying different groups of students that participate in a MOOC. Table 2 shows that the explicit and implicit sequences are associated with behavior, but not valence. One of the possible reasons is that students who participate more in the discussion forum tend to submit more surveys as well but the two types of sequences do not corroborate each other in valence. From Table 3, we also observe that students who feel negatively about the course and then transition to a positive emotional state are more likely to stay in the course. We found that the range of valence that students experience is more indicative of their course completion and quiz performance possibly because the students who struggle through the course report higher valence values after achieving their course objectives, resulting in their highly varied emotions.

A limitation of our work is our sentiment analysis technique that uses a bag-of-words model with the discussion forum records only and does not consider other implicit measures of emotions. In this work, we have only relied on a single word-affect lexicon. However, we can make the calculated valence values more stable by triangulating the valences with other lexicons. We would also like to improve granularity and quantify the extra information conveyed by either type of emotion sequence. Even so, as most emotion research in MOOC relies on only one category of emotions, we conclude that it might be advantageous for researchers in this area to supplement their current method with a method from the other category of emotions. It is important to continue exploring emotions in MOOCs in pursuit of goals such as the personalization of MOOCs, improving the emotional well-

being of students, and the design of MOOCs.

ABSTRACT

Gamification frameworks can aid in gamification planning for education. Most frameworks, however, do not provide ways to select, relate or recommend how to use game elements, to gamify a certain educational task. Instead, most provide a “one-size-fits-all” approach covering all learners, without considering different user characteristics, such as gender. Therefore, this work aims to adopt a data-driven approach to provide a set of game element recommendations, based on user preferences, that could be used by teachers and instructors to gamify learning activities. We analysed data from a novel survey of 733 people (male=569 and female=164), collecting information about user preferences regarding game elements. Our results suggest that the most important rules were based on four (out of nineteen) types of game elements: Objectives, Levels, Progress and Choice. From the perspective of user gender, for the female sample, the most interesting rule associated Objectives with Progress, Badges and Information (confidence=0.97), whilst the most interesting rule for the male sample associated also Objectives with Progress, Renovation and Choice (confidence=0.94). These rules and our descriptive analysis provides recommendations on how game elements can be used in educational scenarios.

1. INTRODUCTION

Gamification has been a widely popular phenomenon in the past few years, being used in various domains, including that of education. Gamification is defined as the use of game elements outside their scope (*i.e.*, games or game playing) [1, 2]. However, educators often may not be familiar with

specific game-related concepts, or know how to use game elements, or may not have the resources or time necessary [3, 4, 5]. A solution is to employ conceptual gamification frameworks [6]. Still, existing frameworks lack resources and explanations on how to use game elements appropriately [5], especially when considering user preferences affected by demographic differences. Understanding users’ characteristics, such as gender, may be especially beneficial, *e.g.*, in STEM education, where the well-known problem of ‘the leaking STEM pipeline’¹ occurs [7].

In this paper, we apply a data-driven approach to provide insights into the educational domain, via the research question: “*How can gender differences in preferences about gamification elements be used to support gamification design?*” We conducted a very large survey (808 raw answers) allowing respondents to rank gamification elements. We based these elements on the works of Dignan [8] and Toda *et al.* [5], due to (a) the relatively large number and variety of elements, (b) the availability of synonyms used. Next, we used an unsupervised learning algorithm to generate Association Rules to find patterns within the dataset, in order to understand relations among these elements, based on the users’ genders. Our main contributions are: (a) a survey² for extracting preferences for gamification for education, applied to a large, varied number of respondents; (b) extracting gamification elements relevant to the different genders, for the educational domain; (c) extracting relations between these elements, relevant to the different genders; (d) insights into users’ acceptance of specific game elements, or groups thereof (and their relations).

2. RELATED WORKS

As there are very few frameworks focusing on gamification in education domains, we discuss: (i) existing models related to game elements, (ii) gamification studies on user characteristics, (iii) planning of gamification.

Armando Maciel Toda, Wilk Oliveira, Lei Shi, Ig Ibert Bittencourt, Seiji Isotani and Alexandra Cristea "Planning Gamification Strategies based on User Characteristics and DM: A Gender-based Case Study" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 438 - 443

Yee and Marczewski both proposed models on how to use game elements, using also large data collections [9, 10]; however, their focus is different: they collected (a) players' motivations towards online RPGs and (b) generic gamified applications. [10] only provides recommendations of elements for behavioural profiles, but not user demographic characteristics, such as gender. Yee's model additionally analysed behaviours from a gender perspective, but only for online RPG (World of Warcraft) players exclusively. A recent study by Shi and Cristea [11, 12] proposed a model and a set of recommendations based on the Self-Determination Theory [13]. Their Motivational Gamification Strategies related game elements with each construct of the SDT, *i.e.*, Autonomy, Competence and Relatedness, and implemented them [11], achieving positive results for each construct. Such studies show how motivational theories and gamification constructs can be related, as well support gamification in education. They however do not support the design process of gamification for educators and teachers.

Denden *et al.* [14] conducted an experiment analysing user preferences ($N = 120$) over eight game elements within a gamified educational system, based on personality traits (the famous 'Big Five' [15]). According to the authors, only extraversion, openness and conscientiousness affected students' preferences for particular game elements. The authors also stated the importance of this kind of recommendation to designers and instructors when gamifying their learning environments. However, the gamification in education literature lacks studies which relate the acceptance and influence of game elements with users' genders, involving large-scale data [16]. One recent study [17] conducted an experimental study aiming at identifying differences between male and female users ($N = 70$) towards 'gaming the system' behaviours. It was shown that game elements led to male users decreasing their undesired behaviours; moreover, female users felt less competent than male users. Nevertheless, although the results are interesting, the number of students who were analysed is still relatively small, with students from within a course context - whereas our study has a wider scale and variety of participants.

Toda *et al.* [5] proposes a framework for blended classroom environments using social networks, via a list of recommendations (names of gamified strategies) based on previous studies in gamification in education. They also apply Dignan's game elements classification [8]. However, the gamified strategies proposed are solely based on literature. Nevertheless, their positive results show that game elements are suited for educational environments (*e.g.*, classroom and digital platforms). As noted, other gamification frameworks focused on specific domains (*e.g.* Computational Thinking [18]). Klock *et al* [19]'s framework is usable for adaptive system. Still, Mora *et al* [6] note that this framework focuses on the researchers, rather than the stakeholders (teachers and instructors) and presents limited recommendations on game elements usage.

Thus, whilst gamification shows potential benefits for educational applications, the gender differences in preference towards specific game elements needed further, large-scale, systematic studies, to better provide support for Data-Driven Gamification Design, as tackled by our current paper.

3. DATASET AND METHODS

Our survey on game elements contains 29 questions. The first part collected demographic information (age, favourite game setting, and gender). The second part asked to what extent certain game elements were relevant to users in the gamified educational system context, through a Likert Scale, from 1 "I think this element is irrelevant to me" to 5 "I think this element is highly relevant to me". The game elements used and their advantages and potential drawbacks are presented in <https://tinyurl.com/y44kqvn5> based on [8] and used in [5] in an educational domain.

Additionally to theoretical motivations, we further validated the selected gamification elements with 4 specialists in gamification, who were also teachers, via an interview, verifying the specialists' acceptance of the used elements, concepts, as well as questions cohesion. Finally, a pilot survey with 18 people verified the time spent and the consistency of the questions, before launching the main survey <https://goo.gl/forms/d0i5WosBcMVWvQAK2>. We then recruited surveyees through social networks, forums and digital environments used by people who play games.

In total, we collected 808 raw answers. Further cleaning removed data from users who: (a) did not answer all questions; (b) claimed not having played any digital games; (c) were of age < 0 or age > 90. Then, we analysed our population characteristics based on demographic data. As the normality test showed a non-normal distribution, a Mann-Whitney test [20] was used to compare males and females.

Finally, we used association rule mining to analyse the relations amongst our data, based on gender. Unsupervised learning was used as we do not have any predefined labels (outputs) and also to understand the relations between the elements (different from clustering which create groups based on all variables of the dataset). The algorithm analyses the items' frequency (support) and renders a level of confidence, ranging from 0 to 1 (where 1 is the maximum confidence). The confidence can also be supported by conviction [21], lift and leverage -- both measuring the independence of items.

4. RESULTS AND DISCUSSION

4.1 Gender differences

After filtering, we retrieved 733 valid answers (90.72%). We applied Cronbach's α on the second group of questions (as game elements were based on a Likert scale) and achieved an $\alpha = 0.83$ (high reliability factor [22]). Our sample is varied in terms of age (ranging from 13 to 68), but limited in terms of experience in playing (at least a year: by design and filtering) and country of origin (Brazil; due to convenience sampling). Nevertheless, the sampling size is much larger than the recommended one ($733 \gg 384$; people playing online games estimated at 700 mio; confidence level 95%).

We further organised our valid answers into two groups: males ($N = 569$) and females ($N = 164$), and verified the distribution of the data using the Shapiro-Wilk normality test. The result showed that our data rejected the null hypothesis ($p < 0.05$), so we adopted non-parametric tests in further analyses. Table 1 summarises the result.

Table 1: Relevance of game elements, averaged per gender

Element	Gender (mean)		Mann-Whitney	
	Female	Male	W	p-value
Point	3.76	3.68	44836	0.429
Level	4.14	4.21	48418	0.427
Cooperation	3.62	3.86	52306	0.013
Competition	3.26	3.56	53016	0.006
Renovation	4.16	3.78	35878	2.36e-03
Progress	4.24	4.32	48856	0.312
Objective	4.41	4.4	45902	0.791
Puzzles	4.14	3.91	40636	0.008
Novelty	4.05	4.16	49530	0.197
Chances	3.68	3.61	44901	0.447
Social Pressure	3.43	3.65	51142	0.05
Acknowledgement	3.85	3.73	44673	0.387
Data	4.05	4.09	46675	0.994
Scarcity	3.16	3.42	52468	0.011
Choice	4.07	4.23	50267	0.08
Time Pressure	3.16	2.97	42711	0.09
Economy	3.41	3.42	46738	0.973
Sensation	3.62	3.1	37094	1.17e-02
Classification	3.51	3.72	51340	0.042

Table 1 shows many significant differences ($p\text{-value} < 0.05$). Interestingly, Competition, Cooperation, Social Pressure, Scarcity and Classification were considered slightly more relevant by the males, whilst Renovation, Puzzle and Sensation elements were considered more relevant by females. Time pressure was disliked by males, but not as much by females.

4.2 Descriptive Analysis

Comparing surveyees, for elements preferred in different proportions, which are statistically significant between males and females, Cooperation was more relevant to males (57.3%); with 41.6% males selecting highly relevant, vs. 31.1% females (Table 2).

Figure 1: Favourite game elements for males (a,b-correspond to Tables 2,3, rsp.)

A more drastic difference appeared when more than 25% of the females did not consider Competition to be relevant, versus 54.5% males. This result suggests that males may perceive social interactions, such as Competition elements and Cooperation, as highly relevant overall in games, with a slight preference of Competition. For females, however, Competition is not that relevant, but, surprisingly, Cooper-

ation is only marginally relevant. Social Pressure is significantly less liked by females (difference of 7.7%).

Table 2: Cooperation, Competition and Social Pressure answers.

Sc	Cooperation				Competition				Social Pressure			
	F	%	M	%	F	%	M	%	F	%	M	%
1	12	7.3	37	6.5	20	12.2	42	7.4	14	8.5	32	5.6
2	20	12.2	53	9.3	25	15.2	80	14.1	26	15.8	63	11.1
3	38	23.8	100	17.6	44	26.8	137	24.1	45	27.4	146	25.7
4	43	26.2	142	25	43	26.2	135	23.7	34	20.7	160	28.1
5	51	31.1	237	41.6	32	19.5	175	30.8	45	27.4	168	29.5

Scarcity was instead favoured (significantly) by males (Table 3), where 37.8% of the females are indifferent. Classification, also a social element, was considered significantly more relevant by males. 50.6% of the females considered it relevant, against 60.6% males (Table 3). Based solely on our descriptive analysis, we observed that the male population considered limited or rare tasks, allowing, *e.g.*, rewards such as interaction or collecting titles, as relevant. Again, in practice, this information allows the teachers to create titles for completing specific tasks during their lectures *e.g.*, by giving a title of 'Speedster' to the student who completes a list of task correctly and quicker than the others.

Table 3: Scarcity and Classification answers

Sc	Scarcity				Classification			
	F	%	M	%	F	%	M	%
1	16	9.8	32	5.6	13	7.9	25	4.4
2	25	15.2	78	13.7	14	8.5	68	11.9
3	62	37.8	189	33.2	54	32.9	131	23
4	39	23.8	161	28.3	42	25.6	163	28.6
5	22	13.4	109	19.2	41	25.0	182	32.0

As for the elements most favoured by females (Figure 2), Renovation scored highest. 76.2% said it was relevant, with 50% considering it highly relevant. In contrast, only 30.0% of the males considered it highly relevant, with almost 30% indifferent (Table 4). In a learning context, this may tell the teacher that female students might be more pleased with features as "continue", "try again" or be given 'extra lives'.

Another element highly relevant to females was Puzzles: 80.8%, against 68.1% of males; with 21.9% males indifferent. Again, females, in this scope, considered that testing their skills was more relevant than males did. The Puzzle and Renovation elements, when combined in practice, allow problem solving, with the opportunity to correct mistakes.

Finally, the Sensation element was considered more relevant by females. More than half (54.8%) of the female sample considered it relevant, against 42.5% of the males. This could be explained by Sensation being related to the user experience [8], and, based on Table 4, we can infer that the most relevant elements for the female sample were related to the experience, rather than social ones. This means that they may perceive tasks that involve their senses, *e.g.*, with a visual or phonetic appeal, as more relevant, which could further be redone whenever they wish, to improve a certain skill through challenges. In practice, this means that using materials and resources that are more visual appealing may be more pleasant to female students than the male ones.

Figure 2: Favourite game elements for the female sample

Table 4: Renovation, Puzzle and Sensation answers

Sc	Renovation				Puzzle				Sensation			
	F	%	M	%	F	%	M	%	F	%	M	%
1	4	2.4	14	2.5	5	3	17	3	12	7.3	108	19

5	82	50	188	33	74	45.2	207	36.4	56	34.1	127	22.3

4.3 Association Rules analysis

To identify the strongest rules for each gender and to verify how the rules found matched or complemented the findings from our descriptive analysis (Section 4.2), we used the Apriori algorithm in Weka, with: (i) minimum support of 10% for the male sample size and 20% for female (to balance sample sizes); (ii) minimum confidence of 90%; and, after applying those attributes, (iii) we used the measures of interest *conviction*, *lift* and *leverage* to find the most interesting rules [23]. Using this setting we found a total of 11 rules for the female sample and 13 rules in the male one.

The majority (>90%) of the rules were based on the Objective element, which suggests its overall popularity. This translates into a general recommendation towards using 'Objective' elements in the educational gamification design, such as missions, milestones and quests, to guide the students. In this work we focused on analysing the most interesting rules in female and male samples. For females, the strongest rules were associated with the Objective (Table 5). The lift > 1 and leverage near 0 indicate that our items are independent and have a positive correlation, and the conviction between 1 and 5 indicates that these are interesting rules. The strongest rule relates Progress, Acknowledgement and Data elements (e.g., Representations of progression, badges and medals and results screen) with Objective (e.g., missions and quests). Rules regarding Progress and Level were also amongst the 10 strongest. Thus, we can suggest that teachers and instructors should use Acknowledgement (such as badges and trophies), with other elements associated with the personal enhancement of users (Progress and Level).

As for the male sample, Objective was also the main element but, in contrast to the females, we did not find any rules (with confidence > 90%) related to elements that were most relevant to the male population (Table 6). There was only 1 rule that specified a social element (Social Pressure)

amongst all the 14 rules. We can observe that Progress appears in almost all the rules, followed by Choice, appearing in seven rules. This means that, in our sample, designers and teachers should consider quests and missions that contain a form of progression and allow the students to make meaningful choices; those choices can be tied to a challenge (Rule 14), to transactions (Rule 24) and points (Rule 16).

Based on the data on Tables 5 and 6, we can observe that Objective associated to Progress is a concept that is (generally) well accepted by both genders. This means that teachers and designers should focus on, e.g., developing quests (which can be tied to their original learning objectives) that allow the learners to place themselves within the task. This is important, since in some educational context, students do not know why they are learning a specific content; and consequently, may become demotivated [24]. In practice, this means that teachers can create milestones or goals, allowing students to visualise their progress towards this goal. Thus, guidelines can be provided to teachers, to convert their objectives in their classes into milestones or quests. Additionally, other representations of Progress, showing the users where they are in the course could be implemented, such as those supported by Levels, Points and Data.

4.4 Further Discussion

We consider this work to be important, as, with the advent of 'big data', various theoretical assumptions and statements can now be backed up by (significant) evidence. In the case of game elements, there is firstly a vast (not always research-based) evidence that games are linked to motivation, and keep players 'in the flow' [25]. Some studies even link specific game elements to higher levels of commitment or motivation [9]. Based on this evidence, as well as theories of motivation, gamification has been proposed for education. Currently, however, the data supporting these assumptions is scarce. There is a lot of small-scale empirical evidence, at classroom-scale, of approaches that showed mixed successes [26, 27]. In a similar way, there is evidence that gamification can also have undesirable effects [28]. This clearly points to the fact that there are parameters which need taken into consideration, which may influence the outcomes of gamified approaches to education. In this study, we specifically focus on demographic parameters - namely, gender.

Gender in education has been brought to the fore recently, with the advent of initiatives such as the 'Athena SWAN'³ initiative towards gender equality in Higher Education in the UK, as well as similar initiatives world-wide. Importantly, equality doesn't mean 'one size fits all': on the contrary, gender equality means that the provision of education takes into account specific preferences that may be gender related. In a similar vein, certain types of games appeal to certain demographics and not others. For instance, card-related games are potentially more appealing to women, and first-player-shooter games to men (although, of course, preferences can vary) [29].

Further analysis of Table 1 shows that male and female preferences of some elements is relatively similar; e.g., Data, Economy, Objective are almost identical, and some are only

³<https://www.ecu.ac.uk/equality-charters/athena-swan/>

23	{level, progress, data, choice}	{objective}	0.91	1.55	0.04	3.92
24	{progress, novelty, economy}	{objective}	0.91	1.54	0.04	3.78
25	{progress, choice, economy}	{objective}	0.91	1.54	0.04	3.78

slightly different. Thus, some game elements may be perceived similarly by males and females - which makes the teacher's job much easier, in terms of design choices. This also puts more emphasis on the game elements where large differences exist, as well as on game elements where the differences in preference are slight, but statistically relevant.

Some of the results obtained were surprising: for instance, we expected females to appreciate cooperation more than males, but results (see section 4.2) showed otherwise. We did, on the other hand, obtain the expected results in terms of preference for competition. It is possible that online social interaction overall is perceived differently by males and females; for instance, females may perceive any type of social interaction online, where people are not known in advance, and anyone from anywhere can participate, as potentially threatening. These types of areas need further analysis.

For educational applications, it may seem that such potential 'fears' are less likely in controlled (classroom, or classroom-based) environments. However, for example, on Massive Online Open Courses (MOOCs), where people can participate from anywhere, such issues can again prevail. In fact, research on social interactions on MOOCs (e.g., comments, etc.) shows a predominance of males performing such activities. In contrast, females preferred puzzles (which can be solved also as solo-player) and the 'Renovation' element

(see Figure 2), which allow for an independent style of play where one focuses only on ones own progress, instead of being interrupted by others.

5. CONCLUSIONS

This work presents our approach based on DDGD, towards planning of gamification in the educational information systems domain by using data mining. The main contribution of our work is to present a poll of gamified strategies tied to male and female genders. Furthermore, we use real data to aid in the decision process of teachers and instructors is selecting gamification strategies. Through our data, we could identify that males would make more use of social interactions, with strong confidence rules pairing gamification elements Progression and Choice. For the females, we identified that user experience and rewards are more relevant, with association rules indicating a strong confidence for the need of Acknowledgement and Progression. We believe that this work can impact the way teachers perceive and apply gamification in their environments, consequently improving students' engagement and motivation through a game-like experience.

Acknowledgement

Grading emails and generating feedback

Abhishek Unnam, Rohit Takhar, Varun Aggarwal
Aspiring Minds

ABSTRACT

Email has become the most preferred form of business communication. Writing *good* email has become an essential skill required in the industry. *Good* email writing not only facilitates clear communication, but also makes a positive impression on the recipient, whether it be one's colleague or a customer. The aim of this paper is to demystify the components of a *good* email and to define a set of parameters by which to grade the quality of an email and provide detailed feedback. This can help candidates improve their email writing skills and also guide tutors. The email grading parameters encompass traditional attributes of written English (i.e. coherent and relevant content and correct grammar) but also include a unique set of characteristics that we may objectively identify as email etiquette. These characteristics comprise the metrics we use to evaluate the quality of the various constituent parts of an email. We grade the email using artificial intelligence, acting on semi-structured text. We use a mix of machine learning and rule-based systems to effectively grade an email on the specified parameters. Our system automatically grades email with accuracy comparable to human graders.

Keywords

Automatic grading; Email Writing; Semi-Structured Text analysis; Education; Supervised Learning

1. INTRODUCTION

In today's knowledge economy, good communication skills (spoken as well as written) are vital for success in the workplace. According to the O*NET taxonomy of jobs and skills [5], 53% of all jobs require a moderate to high level of writing and speaking skills. Lately, there has been a lot of work [18], [10], [17] on automated evaluation of speaking skills. Some of these automated systems help candidates to improve their language-speaking skills [3], [7]. The evaluation of writing skills is generally thought to be confined to academic essay grading [1], [14]. These studies were prompted

by the demand for more efficient evaluation of high-volume educational/academic tests such as TOEFL and SAT. There are job tasks that mimic essay writing such as writing user manuals, product documents or filing Request-for-Proposals (RFPs). However, the writing that is most ubiquitous in companies is email. Interactions with clients and all manner of internal communications with managers, peers, and support services (i.e. human resources, tech support, etc) are carried out via email. Therefore, composing *good* email has become a necessary skill.

We wish to automatically grade email writing skills and provide feedback. This will create a mechanism for students and jobseekers to get feedback on their email writing skills and also provide companies with the ability to automatically test email writing skills of job candidates on a large scale and use the grades in the hiring process. We wish to automatically grade email writing skills and provide feedback. This will create a mechanism for students and jobseekers to get feedback on their email writing skills and outline a path for improvement. It will also provide companies with the ability to automatically test email writing skills of job candidates on a large scale and use the grades in the hiring process. Despite the importance of email writing skills, we have not found any previous work in this area.

We first demystify the components of a *good* email. The grading parameters consist of the traditional attributes of written English (i.e. coherent and relevant content and correct grammar) but also include a unique set of characteristics that we objectively identify as email etiquette. We have identified a set of 36 metrics on which to evaluate the quality of the various constituent parts of an email. Many of these metrics are derived from the general norms of communication, while others are specific to the written form of email (discussed in detail in Section 2). Our aim is to automatically grade email on each of these metrics.

We grade email using artificial intelligence, acting on semi-structured text. Some parts of an email are structured, such as the subject, salutation and sign-off (Figure 1). The body of the email, a set of sentences, is unstructured. There are multiple approaches to grading structured and unstructured text. Essay grading [4] and the grading of short answers [13] are examples of unstructured text grading. Generally, researchers generate a set of features such as bag of words, word embeddings, parts-of-speech (POS) tags, etc. and use supervised or semi-supervised learning to predict grades. The grading of computer programs which use tightly defined grammar is an example of structured input grading. In [15] authors derive sophisticated features by exploiting the

Abhishek Unnam, Rohit Takhar and Varun Aggarwal "Grading emails and generating feedback" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 444 - 449

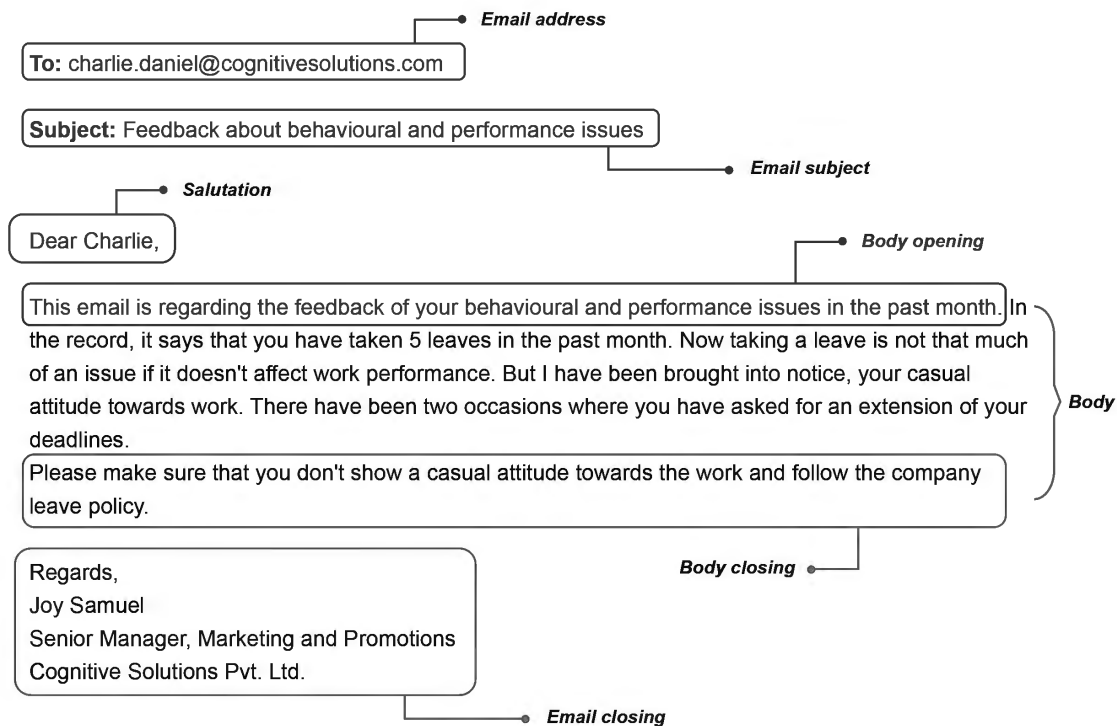

Figure 1: Sample email being written by a student.

structure of the program by drawing control row and data dependency graphs. Whereas, resume parsing is an example of processing semi-structured text [2].

We propose a mix of machine learning and rule-based models to grade the various quality metrics of an email. We find that such an approach works well for semi-structured text and for a variety of evaluation parameters. We show that generally the rule-based models work well for processing the structured parts of email and for grading email on etiquette. On the other hand, content relevance and grammar are better graded via machine learning. Interestingly, for some attributes, a mix of both models work best. Our approach stands contrast to recent trends that apply machine learning to all tasks indiscriminately.

We derive a number of natural language features for our machine learning models. We use supervised learning to build the models. The rule-based models use word lists and regular expressions. Our algorithm provides accuracy that rivals expert consensus. Our final system generates separate grades for content relevance, grammar and email etiquette. It also provides detailed feedback on the types of errors that occur in each part of the email. In particular, the paper makes the following contributions:

- We propose the first viable system for automatically grading email writing skills and delivering constructive feedback.
- We demystify the components of *good* email and provide objective evaluation criteria.
- We propose a mix of machine learning and rule-based models for evaluating emails. The accuracy of our system rivals expert consensus.

- We provide first-of-its-kind data-based insight into the errors committed by students and jobseekers.

The paper is organized as follows. In Section 2, we describe the metrics we define for evaluating email etiquette. In Section 3, we discuss the methods used to evaluate the metrics. In Section 4 we explain the experiments, datasets and models that have been developed for grading. In Section 5 we present our results by comparing the performance of our system with that of human experts. Concluding remarks are provided in Section 6.

Response	Status
I care for this in an email that I receive	agree
I may care for this in an email that I receive	not sure
I do not care for this in an email that I receive	disagree

Table 1: Each rule was put into one of these categories

2. EMAIL ETIQUETTE

Quality metrics for evaluating email writing skills go beyond the parameters traditionally defined in the grading of written language, i.e. paragraphs and essays.

Email as social communication must follow certain norms. Some of these norms are derived from the general norms of verbal communication, while others are specific to the written form of email. These norms manifest themselves as rule sets for the structured fields of email and the unstructured body. A simple rule is that values for all the structured fields should be present. For example, an email that lacks a subject line is

Quality Metrics	Explanation & Examples	Counts
Missing	Missing subject line, salutation, signoff etc. Subject: Email Body: This is to inform you that....	3
Redundancy	Starting the subject line with terms such as ‘regarding’, ‘response to’. Subject: regarding behavioral and performance issues.	6
Word usage	Incorrect usage of words in various sections of an email - using names/greetings in subject line, usage of informal, abbreviated words etc. Subject: Employee feedback for Charlie Daniels Email Body: Hi Daniel, Can u pls respond quickly...	10
Style	Errors specific to conventions like greeting and sign-off style. Email Body: Hella Daniel/Heyy Charlie Daniels/Hi Mr Charlie Daniel Yours Sincerely/Truly/faithfully Mr Charlie Daniel	7
Emotional Punctuation	Errors like using too many commas inside a sentence, using exclamation/semi-colons marks inside subject/salutation/closing, using all uppercase words in subject line etc. Subject: POOR performance !!! need improvement Email Body: Heyy!! Charlie, HI CHARLIE please reply...Thanks, Alisha	5
Punctuation	Capitalisation errors like starting subject line with lowercase, proper nouns starting in lowercase etc. Not giving space after fullstop. Subject: feedback on performance Email Body: hi charlie daniel, This is to inform you about the poor performance in last financial year.I have seen many instances of work lapse.	5

Table 2: Quality metrics with explanations & examples.

not good. A rule derived from verbal communication norms is that the opening greeting should not address the recipient by both first and last name, and that a title should be added when addressing a person by last name only. An example of a rule typical to the written form is that the subject line should not be longer than a given length. Another example is that no words (except acronyms) should appear in all upper case, and that emoticons should be avoided. There are also other metrics that derive from the changing norms of communication. In today’s business world, one doesn’t address others as ‘Respected’ and rather use a ‘Hi/Hello/Dear’. There are similar rules that govern the body of an email.

There are additional regarding the purpose of the email, or in a grading scenario, the prompt of the email writing task. For example, when responding to an irate customer, one should not employ the oft-used email phrase “Hope you are doing well”. Similarly, the closing line of an email may depend on the prompt. Emails that seek a response may conclude with, “I look forward to your response”, while a simple conversation may end with simply “Feel free to reach out to me”. There is no standard list of these rules. We looked at the various blogs and documents with email writing rules to put together a super-set of 57 different possible rules. We shared these rules with three professionals from India and three from US, each with 10+ years experience in the corporate world. Two from each country were from either the IT, banking or contact center industry. Three were involved in external communications, while another three were into internal com-

munications. We asked them to rate each rule as in Table 1. From the original 57 rules, we selected the 36 on which four

Section	Number of errors
Subject	9
Salutation	6
Email Body	13
Closing	8

Table 3: Section-wise error counts.

or more of the professionals agreed. These 36 rules became our quality metrics, which we categorized into 6 broad categories with definitions (See Table 2). In Table 3, we show the number of rules that apply to each part of an email. We evaluate an email against each of these rules and delineate the errors in a candidate feedback section. We also provide a total score for email etiquette. This score is based on the number and severity of errors made. For example, a *missing* error is more severe than *redundancy* errors. We also include the standard parameters and rubrics [8] of English evaluation: content relevance and grammar.

3. METHODS USED

We used three different methods to evaluate the various facets of quality metrics. We use a mix of rule-based and machine learning methods.

3.1 Word list-based

Many email etiquette errors may be detected simply by presence or absence of certain words or phrases. For instance, an email should not have abusive words or slangs. On the other hand, a pleasing email shall have words like ‘thank you’, ‘please’, ‘request’ etc. We created word-lists to evaluate such metrics in an email. Such an approach has also been followed earlier in emotion detection [16]. The words in email are matched against the word lists after stemming. Based on the occurrence and counts (normalized, in some cases), the feedback and scores, are respectively generated. For instance, if someone writes “Whoa, It was great working with u.” we provide a feedback to avoid the usage of informal words like ‘whoa’ and ‘u’. We graded 19 error metrics in this manner using 26 word lists¹. The efficacy of this approach was tested by evaluating the generated feedback and score against human expert feedback. This is described in Section 4.

3.2 Pattern-based

Certain metrics were evaluated not by the occurrence of a single word or phrase, but based on an expected pattern. For instance, the recipient may be addressed by using more than one combination of the greeting (Dear/Hi/Hey), title (Mr/Ms/Dr), first name and last name. Some combinations are right (Dear First Name), while some are wrong (Dear Last Name). The correct and incorrect patterns were coded into regular expressions, to provide exact detection of an error and providing feedback (e.g., ‘Do not use only last name without title’). One may note that this detection assumes we know the full name of the recipient. For every email writing task (prompt), certain structured information such as recipient name, company name, sender name and certain keywords is generated at the beginning (manually). This is used for various error detection including, for example, capitalization, and spelling errors. In total, 16 error metrics were evaluated using pattern matching.

3.3 Regression-based

We use supervised learning to grade an email on content relevance and grammar. We train regression models using a number of different features to predict expert grades. We now describe the features used for each of the two parameters.

3.3.1 Content Relevance

The candidate’s task was to write an email according to the situation provided in the prompt. We wish to evaluate whether the content properly addresses the situation, is comprehensive, coherent and without unnecessary information. This metric is linked to the semantics of the email only and doesn’t evaluate other parameters such as the emotion of the email. We describe the natural language features used for the task.

- **Word embeddings:** Here, we used the Word2vec model [11], particularly Google’s pre-trained model developed with a vocabulary over 3 million words and phrases and trained on roughly 100 billion words from Google’s news dataset. For each word in the email we first calculate a 300-length lower dimensional vector and then sum it across all the words in the email.

¹For some error metrics more than one word lists were used.

- **Bag of Words (BOW):** We used the bag of words feature-counts of unigrams, bigrams and trigrams. All the words were stemmed and stops words were removed.
- **Prompt Overlap:** We calculated prompt overlap in two ways: *exact match* and *extended match*. In *exact match*, we count the number of common words between the prompt and the email. In *extended match*, we add the synonyms of all words in the prompt using WordNet [12]. We then count the number of common words between the extended prompt word list and the words in the email.

3.3.2 Grammar

Below are the features we used to evaluate the grammatical correctness of Here our aim is to evaluate the grammatical correctness of the email. We use the following features:

- **Bag of POS tags:** Here, words are assigned to their respective part of speech (POS) tags using the Penn Treebank NLTK tagger [9]. We then considered bigrams and trigrams of POS tags. This feature removes the semantic information from the words, while preserving the sentence structure and grammatical features.
- **Error Counts:** We also use counts of the grammatical errors in the email as identified by open-source grammar correction tools.
- **Proportion of good tags:** Here, we wish to find the similarity of the language in the email with that of a grammatically correct corpus. We used Brown corpus [6] for our purpose. We generated bag of POS bigrams and trigrams from this corpus. We consider the top 70% most frequently occurring POS bigrams and trigrams as a set of *good n-grams*. We then find what proportion of n-grams in the email are *good n-grams*.

4. EXPERIMENTS

We had designed our experiments to answer the following questions:

- How accurate is our approach in predicting content and grammar scores as compared to human experts?
- How accurately do we detect email etiquette errors using the word list and the pattern matching methods?
- What proportion of errors marked by humans experts do we correctly detect and how many false errors do we generate?

We conducted our experiments on a set of 1200 emails which were manually rated by human experts. For training models, we made use of both linear (linear, ridge regression) and non-linear (random forest(R.Forest), SVM) techniques. We discuss more about the dataset in the next section.

4.1 Dataset

Our dataset consists of 1200 emails in response to three different prompts. We used an equal set of 400 emails per prompt, after removing any blank email or those with very little content. These samples were collected from both undergraduate and graduate students. The candidates were given a situation and asked to write an email to address the situation. The three situations included a customer service situation where one needs to address a customer’s complaints, a sales situation where one probes the requirement of a prospect and

		Prompt 1		Prompt 2		Prompt 3	
Model	#Features	Train (r)	Validation (r)	Train (r)	Validation (r)	Train (r)	Validation (r)
Linear	50	0.86	0.79	0.87	0.81	0.85	0.77
Ridge	50	0.86	0.80	0.87	0.81	0.84	0.77
R.Forest	150	0.95	0.80	0.95	0.82	0.92	0.79
SVM	50	0.84	0.79	0.86	0.80	0.83	0.76

Table 4: Performance of prompt-specific content models.

		Validation				
Model	#Features	Train (r)	Overall (r)	Prompt 1 (r)	Prompt 2 (r)	Prompt 3 (r)
Linear	75	0.77	0.62	0.59	0.65	0.65
Ridge	75	0.70	0.66	0.62	0.67	0.75
R.Forest	150	0.85	0.73	0.71	0.73	0.74
SVM	150	0.62	0.60	0.52	0.59	0.74

Table 5: Performance of grammar models trained on complete set of emails. We present the overall and prompt wise validation correlations(r).

promotes a service and a people management situation where one needs to give feedback to an employee on performance issues. The responses were collected using *AMCAT*², our proprietary computer based testing platform.

All email responses were graded by human experts. Content Relevance and Grammar were graded based on a 7 point and 5 point rubric respectively. Detailed guidelines were provided for identifying each email etiquette error. The experts had to mark the exact location where the error occurred and the category of the error. Each email was graded by 3 different experts. These included an English language trainer, a sales manager and a customer service manager. Each of these had an experience of more than seven years in the industry. The experts first went through a three-day training where they learned how to interpret the rubric and were subjected to practice grading exercises.

We achieved an average inter-rater correlation 0.83 for content scores and 0.74 for the grammar scores. For email etiquette, only those errors were considered where atleast two experts had a consensus. A consensus was reached for 83% of the total cases.

4.2 Models

For content relevance we trained different models for each prompt, while for grammar, a generic model was trained across all prompts. For each model the corresponding dataset was divided into train and validation sets. We used a stratified 70-30 split for train-validation sets. We used linear regression, linear regression with L2 regularization (ridge), SVM and R.Forest to train models. Select K-best algorithm was used for feature selection. The models with the lowest cross-validation (4-fold) error were selected.

For the rule-based system, we used 50% of the email sets to experiment with the rules, patterns and word-lists. Several iterations were performed to fine tune the algorithm. The rules were then tested on the remaining 50% data. We report the results on this validation set.

²<https://www.aspiringminds.com/contentTech>

5. RESULTS

We evaluate our machine learning models using the Pearson correlation coefficient between predicted and the expert grades. We report and discuss results for the validation set. For content evaluation, all modeling techniques provide similar results. The correlation for all prompts is around 0.79 (refer Table 4). For grammar scores, *R.Forest* gives the best results, though marginally better than other techniques. Here, we created one model across prompts and the overall correlation across prompts is 0.73. Also, the correlation value of any individual prompt is more than 0.71 (refer Table 5). For email etiquette errors, we report two metrics of errors:

Error Category	Counts(%)	TP(%)	FP(%)
Redundancy	31.27	70.00	17.86
Missing	69.77	93.55	11.29
Punctuation	90.78	94.12	19.17
Emotional Punctuation	18.00	84.48	6.90
Style	95.74	95.11	8.27
Word usage	17.05	100.00	20.00
Average	53.76	89.54	13.91

Table 6: Category wise performance of rule based system for email etiquette.

- **TP (True Positives):** It is the proportion of expert errors that were correctly identified. An error is deemed correctly identified only when the position and error type is correct.
- **FP (False Positives):** It is the number of non-existent errors identified, normalized by the total count of expert errors. This provides an idea of the proportion of extra errors detected.

We report all the values for the unseen validation set, 50% of the total data. We present the category-wise and section-wise results in Table 6 and Table 7 respectively. **Counts(%)** (in Table 6 and 7) states the percentage of emails that had the given error. This provides some interesting insights. For

Section	Counts(%)	TP(%)	FP(%)
Subject	70.41	70.59	8.82
Salutation	79.84	92.78	17.53
Closing	94.88	95.28	11.02
Email Body	77.43	89.83	10.10

Table 7: Section wise performance of rule based system for email etiquette.

instance, we find that most students make an error in the email closing, followed by salutation and the least number of errors in writing the subject line. On the other hand, the most number of emails are impacted by errors in style and classical punctuations. When we analysed in detail, we find that the *style* of the *closing* has the most number of errors. Candidates either completely miss the sign-off or use overly formal phrases like ‘Yours Truly/Sincerely/faithfully’. We find that the average TP is 89.54% and FP is 13.91%. One may recall that the expert consensus was achieved in 83% of the cases. Our system detects most of the expert-identified errors and has a low rate of detecting false errors. Further, we find that the lowest TP rate for any category is 70% (*redundancy*) and highest FP rate is 20% (*word usage*). There are only two categories with either a TP rate less than 80% or a FP rate of more than 20%. On the other hand, the lowest TP is for the *subject* (70.6%) and highest FP is for *salutation* (17.5%) yet under the 20% mark. We ultimately aim to get all error rates in the 80-20 range of TP-FP.

6. CONCLUSION

We propose a system to grade email on content relevance, grammar and email etiquette using a mix of rule based and machine learning methods. We present a set of 36 quality metrics to evaluate email etiquette, their broad categorization and explanation. Our automated system provides human competitive performance on all evaluation parameters. The system provides scores on the three parameters and also detailed feedback on email etiquette. This feedback comprises the exact location of error, details of the error, and possible corrections.

In future, we plan to work on grading the finer aspects of email writing skills, such as flow of the email, its sentiment and how well the different parts of the email address the situation in the prompt. Also, this is a new interesting approach to process semi-structured text. We plan to use and benchmark the approach for other applications.

ABSTRACT

Massive Open Online Courses (MOOCs) have become more and more popular recently. These courses have attracted a large number of students world-wide. In a popular course, there may be thousands of students. Such a large number of students in one course makes it infeasible for the instructors to grade all the submissions. Peer assessment is thus an effective paradigm that can help grade the submissions at a large scale. However, due to the variance in the ability and standard of the student graders, peer grades may be noisy and biased. Aggregating peer grades to have an accurate and fair final grade for a submission is a challenging problem because the reliability and bias degrees of graders are usually unknown in practice. To address this issue, some probabilistic models considering the graders' reliability and bias are proposed. However, due to the sparsity of peer grade observations, it is difficult for these models to estimate the accurate reliability and bias of the graders as well as the true grades of the submissions. Compared with absolute peer grades, the relative peer grades, derived from the difference between the peer grades of two submissions graded by the same grader, are less sparse and more robust to the grader's bias. Thus relative peer grades are informative and helpful in cardinal peer grading estimation whose goal is to estimate the absolute numeric grades of submissions. In this paper, we propose two new probabilistic models to help improve the accuracy of cardinal peer grading estimation using the observed relative grades among submissions. In this way, the relation between the true grades among submissions is taken into consideration when deriving the final grades. Experimental results on real MOOC peer grading datasets show that the proposed models outperform baselines and the relation of true grades among submissions indeed contributes to the improvement in the grade estimation.

1. INTRODUCTION

Massive Open Online Courses (MOOCs) have provided millions of learners with open access to high quality courses via web. For a popular course, there may be thousands of students. Recently, several MOOC platforms offer verified certificates or even degree programs, and peer grading plays an important role in the student performance evaluation. The benefit of peer grading is two-folded. On one hand, it is helpful for the instructors to evaluate students performance, which is otherwise infeasible due to the large number of enrollment. On the other hand, it is also beneficial to the students: they can see peers' work from different aspects and increase their involvement in the course [5]. Especially, peer grading can be used when automatic grading cannot be applied, for example, on essays and projects. A typical process of peer assessment includes two steps: first, students are assigned to grade a subset of submissions and then the platform aggregates these peer grades to compute the final grades of these submissions.

Although peer grading is helpful, it is a challenging problem to aggregate these peer grades and determine the final grade of a submission. In this paper, we consider the case of cardinal peer grading (i.e., each submission receives a numerical grade as the final grade). Most platforms use the median of received peer grades as the final grade of a submission. However, the median grade may be inaccurate due to the different reliability and bias degrees of graders. Usually, the difference between the grade given by a grader and the true grade of the submission can be decomposed into bias and reliability degree. Suppose a grader grades multiple submissions, and then the bias represents the difference between the mean grades of this grader and the true grades on these submissions. The reliability degree of the grader is measured by the variance of the difference between the the grades that the grader gives and the true grades of these submissions. If a grader randomly assigns grades to the submissions, he/she is not a reliable grader. If the variance is small, then a grader grades the submission in a consistent way and is thus a reliable grader. It is important to consider the modeling of grader bias and reliability to derive more accurate estimates of the final grades. Therefore, there are some existing efforts towards this direction [7].

However, the mechanism of peer grading that each student only grades a small subset of submissions leads to a data sparsity issue. The sparsity of the observed grades makes these models difficult to correctly estimate reliability, bias

of the grader and the true grades of the submissions. In addition the observed grades are sensitive to the grader's bias. Compared with absolute observed grades, the relative peer grades between two submissions are less sparse and more robust to the grader's bias, since the relative peer grades are derived from the difference of the grades assigned by the same grader to two different submissions. Thus the relative peer grades are informative in estimating the true grades of submissions. However, all existing cardinal peer grading estimation models [7, 6, 2] only consider the absolute peer grades of each submission. None of these models considers the relative grades between two submissions.

Recognizing the importance of relative peer grades, we develop new probabilistic graphical models by leveraging relative peer grades between submissions to model the dependency between the true grades. The proposed probabilistic models estimate the true grades of submissions from the peer grades as well as relative peer grades by modeling the bias and reliability of graders. Gaussian distributions are applied to model the true grades, the bias of grader, the absolute peer grades, and relative peer grades in the proposed models. Two different distributions are proposed to estimate the reliability of the graders. In the first model, the reliability of the grader follows a Gamma distribution with the shape parameter determined by the grader's own true grade, while in the second model, it follows a Gaussian distribution with the mean equal to the grader's true grade. To evaluate the proposed models, experiments are conducted on peer grading datasets collected from a popular MOOC platform in China. Experimental results show that the proposed models improve the accuracy of the cardinal peer grading estimation by considering the dependency of true scores between two submissions. The main contributions of this paper are summarized as follows:

- We find that relative peer grades among submissions can help improve cardinal peer grading estimation accuracy.
- We propose new probabilistic graphical models by incorporating observed relative grades to model the dependency between the true grades of these two submissions.
- We evaluate the proposed models on real peer grading datasets and experimental results show that the proposed models can improve the accuracy of cardinal peer grading estimation.

2. RELATED WORK

Existing work on peer assessment aggregation can be divided into two categories based on the data types: the cardinal and ordinal peer grade estimation. The goal of ordinal peer grade estimation is to rank the students according to their submissions. Models based on pair comparison [10, 8], Bayesian generative approach [12] and matrix factorization are developed for the ordinal peer grades estimation [1].

For cardinal peer grading estimation, students are asked to grade their peers' submissions by assigning a specific numerical grade and the aim of cardinal grades estimation is to find the absolute true scores of the submissions. Below we summarize the existing work related to cardinal peer grading estimation respectively.

One major approach of cardinal peer grading estimation is to

update grades and grader weights iteratively [4, 12, 3]. Another major category of methods are based on probabilistic graphical models [7, 6, 2]. The proposed models in this paper fall into this category. The main idea is to model the true grade of a submission, the reliability and bias of each grader as hidden random variables following certain distributions, and infer the model parameters by fitting the models on observed peer grades. In particular, the following methods [7, 6] (referred to as PG_1 to PG_5) are the most relevant to our proposed model. In [7], three probabilistic graphical models named PG_1 , PG_2 and PG_3 are proposed. PG_1 is the basic model, which assumes that true grades, observed peer grades, and biases follow Gaussian distributions and the reliability of the grader follows a Gamma distribution. Upon PG_1 , PG_2 links the bias of a grader among assignments, and PG_3 couples the grader's grade of his/her submission and the grader's reliability. In PG_3 , the grader's reliability is modeled as a linear function of the grader's grade. To relax this assumption of linear relationship, two extensions of PG_3 referred as PG_4 and PG_5 are later proposed in [6]. Both PG_4 and PG_5 assume the reliability of a grader is related to the grader's own grade, and use either Gamma distribution or Gaussian distribution to model this reliability. Recently, social connections are also considered in the modeling of the dependencies of bias among students [2].

However, all existing cardinal peer grading estimation methods only consider absolute grades. In these methods, the true grades of different submissions are treated independently. None of these models takes the relative grades into consideration. In fact, leveraging the relative grades between submissions to model the dependency between true grades of these two submissions can help reduce the noise introduced by the bias of graders and alleviate the data sparsity issue, and thus can help to improve the accuracy of cardinal peer grading estimation. To the best of our knowledge, this is the first work that integrates relative grades into cardinal peer grading aggregation to achieve improved estimation.

3. PROBLEM DEFINITION

In this section, we first introduce some concepts and notations used in the rest of this paper. Then we formally define the problem.

The set of all the students is denoted as S and the set of all the graders is denoted as G . Under the peer grading setting, $G \subseteq S$, since the graders are students as well. The observed absolute grade (peer grade) of a submission submitted by student i graded by grader g is denoted as z_i^g , and the observed relative grades (relative peer grades) between submissions submitted by students i and j graded by grader g is denoted as d_{ij}^g . The relative peer grades are derived using absolute peer grades, which are the difference of the absolute peer grades. For example, if a grader g assigned a score of 4 to the submission submitted by student i and a score of 6 to the submission submitted by student j , then z_i^g is 4 and z_j^g is 6. We can derive that the relative grade $d_{ij}^g = z_j^g - z_i^g = 6 - 4 = 2$. The subset of students whose submissions are graded by an arbitrary grader $g \in G$ is described as S_g and the set of graders who assign grades to the submission submitted by student i is defined as G_i .

With these definitions introduced, we define the cardinal peer grading estimation problem as follows: Given a set of

students S , a set of graders G , a set of peer grades $\{z_i^g\}_{i \in S, g \in G}$ and relative peer grades $\{d_{ij}^g\}_{i, j \in S, i \neq j, g \in G}$, we want to estimate the true absolute grade for submission submitted by student i , $\forall i \in S$, and to learn the reliability and bias for each grader g , $\forall g \in G$.

4. METHODOLOGY

In this section, we describe our probabilistic graphical models named PG_6 and PG_7 for cardinal peer grading estimation. Both models specify a two-stage generation for the peer grades and relative peer grades. The first stage specifies the generation of graders' bias, reliability and true scores of submissions and the second stage generates the peer grades and relative peer grades given the grader's bias, reliability as well as the true scores of submissions.

True score generation: In the proposed models, the true score of the submission submitted by student i is modeled as a random variable following a Gaussian distribution.

Grader bias generation: The bias of grader g is denoted as b_g , which measures the constant grade inflation or deflation of a grader. We model the grader's bias as a random variable following a Gaussian distribution. Though different graders may have different bias, we can assume the average of all graders' bias is 0.

Grader reliability generation: The reliability of a grader reflects how consistent a grader assigns grades. A reliable grader keeps a stable bias when assigning grades to different submissions. Following the assumptions in [11], we assume that the reliability of a grader is related to his/her own grade, which reflects the grader's knowledge about the assignment. We assume that the grader with a higher grade of the assignment may be a more reliable grader for submissions of the same assignment. The reliability of a grader g is denoted as τ_g and modeled as a random variable following a Gamma distribution in the PG_6 model and a Gaussian distribution in the PG_7 model, respectively. In the PG_6 model the grader's true grade is used as the shape parameter of the Gamma distribution, while in the PG_7 model it is used as the mean value of the Gaussian distribution.

Peer grade generation: After generating the bias and reliability of graders as well as the true scores, the peer grades can be generated with these variables. The peer grade is modeled as a variable following a Gaussian distribution whose mean is the sum of the true grade of the submission and the bias of the grader, and its variance is inversely proportional to the reliability of the grader. In the PG_7 model, we introduce a hyper-parameter λ to tune the scale of the variance.

Relative peer grade generation: To incorporate more observations to estimate the reliability and bias of the grader and the true grade of the submission, the relative peer grade is generated. The generation of relative peer grade provides us with another view of true score of a submission in addition to the traditional way that models the true grade as the sum of observed peer grade and the bias of the grader. With the relative peer grade, the true grade s_i of submission i can be estimated by the sum of the true grade s_j of submission j and the relative peer grade between these two submissions. In such a way, the influence of grader bias is excluded.

Similarly to the generation process of peer grade, the relative peer grade is generated with the given true grades of

Figure 1: The plate notation of the PG_6 and PG_7 model.

Table 1: Notations

Notation	Description
S	set of all students
G	set of all graders
τ_g	reliability of grader g
b_g	bias of grader g
s_i	true grade of submission from student i
z_i^g	observed grade of submission from student i by grader g
d_{ij}^g	observed grade differences between submissions from student i and j by grader g

two submissions and the reliability of the grader. We assume the relative peer grade follows a Gaussian distribution with mean value equal to the difference of the true grades between two submissions and variance inversely proportional to the grader's reliability. Also, in the PG_7 model, λ is used to specify the scale of the variance.

Figure 1 shows the graphical structure of the PG_6 and PG_7 models. The box in the middle indicate a grader g and the first and last box indicate student i and j whose submissions are graded by grader g . Table 1 summarizes the notations of variables.

In the PG_6 model and PG_7 model, the grader's reliability τ_g and bias b_g and the submission's true grade s_i are the latent variables that need to be estimated. However, these latent variables are related to each. To estimate the values of these latent variables, Gibbs sampling is applied in this work to draw samples of a latent variable from an approximated posterior distribution. After enough iterations, we discard the first few burn-in iterations and we use the mean value of sampled s_i as the final estimate of the true score of submission i . For s_i in PG_6 and τ_g in PG_7 , we cannot find a closed form of the posterior distribution, so we use a discrete approximation to get the approximate posterior distribution of these two variables. Next we will describe the details of generation process and the inference of the PG_6 and PG_7 model separately.

4.1 The PG_6 Model

The generative process of the PG_6 model is as follows:

- For each submission submitted by student i
 - Draw true grade $s_i \sim \mathcal{N}(\mu, \frac{1}{\gamma})$
- For each grader g
 - Draw bias $b_g \sim \mathcal{N}(0, \frac{1}{\eta})$
 - Draw reliability $\tau_g \sim \Gamma(s_g, \beta)$
- For each peer grade z_i^g submitted by grader i graded by grader g
 - Draw peer grade $z_i^g \sim \mathcal{N}(s_i + b_g, \frac{1}{\tau_g})$

- For each relative peer grade d_{ij}^g between submissions submitted by student i and j graded by grader g
 - Draw relative peer grade $d_{ij}^g \sim \mathcal{N}(s_i - s_j, \frac{2}{\tau_g})$

In the PG_6 model, the posterior distribution of the true score of submission s_i does not have a closed form. To have an approximate distribution of this latent variable, in this paper, we discretized the true score of submission s_i from 0 to 15 (the full mark of the assignment) with an interval of 0.1. The variables are updated according to Eq. 1.

$$\begin{aligned} b &\sim \mathcal{N}\left(\frac{\sum_{i \in S_g} \tau_g (z_i^g - s_i)}{\eta + |S_g| \tau_g}, \frac{1}{\eta + |S_g| \tau_g}\right) \\ \tau &\sim \Gamma(s_g + \frac{|S_g|^2}{2}, \beta + \frac{\sum_{i \in S_g} (z_i^g - s_i - b_g)^2 + \sum_{i,j \in S_g} \frac{1}{2} (d_{ij}^g - (s_i - s_j))^2}{2}) \\ s &\propto \frac{\beta^{s_i} \tau_i^{s_i-1}}{\Gamma(s_i)} \times \exp\left(\frac{-R}{2} (s_i - \frac{Y}{R})^2\right) \end{aligned} \quad (1)$$

where $R = \gamma + \sum_{g \in G_i} (\frac{1}{2} \tau_g (|S_g| + 1))$, and

$$Y = \mu\gamma + \tau_g (\sum_{g \in G_i} (z_i^g - b_g) + \sum_{g \in G_i} \sum_{j \in S_g} \frac{(d_{ij}^g + s_j)}{2}).$$

4.2 The PG_7 Model

The difference between PG_7 model and PG_6 model lies in the grader reliability generation: PG_7 adopts Gamma distribution while PG_6 adopts Gaussian distribution. The generative process of the PG_7 model is as follows:

- For each submission submitted by student i
 - Draw true grade $s_i \sim \mathcal{N}(\mu, \frac{1}{\gamma})$
- For each grader g
 - Draw bias $b_g \sim \mathcal{N}(0, \frac{1}{\eta})$
 - Draw reliability $\tau_g \sim \mathcal{N}(s_g, \beta)$
- For each peer grade z_i^g submitted by grader i graded by grader g
 - Draw peer grade $z_i^g \sim \mathcal{N}(s_i + b_g, \frac{\lambda}{\tau_g})$
- For each relative peer grade d_{ij}^g between submissions submitted by student i and j graded by grader g
 - Draw relative peer grade $d_{ij}^g \sim \mathcal{N}(s_i - s_j, \frac{2\lambda}{\tau_g})$

In this model, the posterior distribution of the reliability of a grader τ_g does not have a closed form neither and we apply discrete approximation to approximate the posterior distribution of grader's reliability from 0 to 15 with an interval of 0.1. The variables are updated according to Eq. 2.

$$\begin{aligned} b &\sim \mathcal{N}\left(\frac{\sum_{i \in S_g} \frac{\tau_g}{\lambda} (z_i^g - s_i)}{\eta + |S_g| \frac{\tau_g}{\lambda}}, \frac{1}{\eta + |S_g| \frac{\tau_g}{\lambda}}\right) \\ \tau &\propto \tau_g^{\frac{|S_g|^2}{2}} \times \exp\left(\frac{-\beta}{2} [\tau_g - (s_g - \frac{\sum_{i \in S_g} (z_i^g - s_i - b_g)^2}{2\lambda\beta} - \frac{\sum_{i,j \in S_g} (d_{ij}^g - s_i + s_j)^2}{4\lambda\beta})]^2\right) \\ s &\sim \mathcal{N}\left(\frac{Y}{R}, \frac{1}{R}\right) \end{aligned} \quad (2)$$

where $R = \gamma + \beta + \sum_{g \in G_i} \frac{\tau_g}{\lambda} + \sum_{g \in G_i} \frac{\tau_g * (|S_g| - 1)}{2\lambda}$, and

$$Y = \gamma\mu + \beta\tau_i + \frac{\tau_g}{\lambda} (\sum_{g \in G_i} (z_i^g - b_g) + \frac{\sum_{g \in G_i} \sum_{j \in S_g} (d_{ij}^g + s_j)}{2}).$$

Table 2: Dataset Statistics

	Question1	Question2	Question3
# of graders	100	237	105
# of submissions	126	288	141
# of peer grades	493	1121	516
# of instructor grades	114	257	123
full grades	15	15	15
observed mean	6.8	6.7	6.2
observed variance	0.11	0.12	0.14

5. EXPERIMENTAL RESULTS

We perform experiments on a real-world dataset with three questions to evaluate the performance of the proposed models, and we show the results in this section.

5.1 Dataset

The real dataset including peer grades for three questions was collected from a course named "Immortal Arts: Approaching the masters and classics" on the XuetangX platform¹. For each question, students are asked to write an essay between 100 and 250 words. The peer graders for each submission are automatically assigned by the platform and the grading process is double-blind. After receiving the peer grades, the platform uses the median of peer grades as the final grades for submissions. The grades assigned by TAs are also available in this dataset, which we use as ground truth (true score) in evaluation. The overall statistics of this dataset is shown in Table 2.

5.2 Baselines

In order to evaluate the effectiveness of the proposed models, we compare them with 6 baselines, which are discussed as follows. including the median of peer grades, the mean of peer grades, the PG_1 model and the PG_3 mode in [7] and the PG_4 model and PG_5 model in [6].

- Median: This approach takes the media of peer grades as the final grade. This is the most frequently used method to aggregate peer grades in MOOC platforms such as Coursera² and XuetangX platform.
- Mean: This approach simply assigns the mean value of peer grades as the final grade to a submission. In some cases, using the mean value of peer grades as the final peer grades may achieve good performance according to [9].
- PG_1 : This is the first probabilistic model for cardinal peer grading estimation that considers the reliability and bias of graders [7].
- PG_3 : This is a probabilistic model that links the grader's reliability with the grader's own grade. This model assumes that the variance of distribution for the peer grades is inversely proportional to a linear function of the grader's grade [7].
- PG_4 : This is a probabilistic model assuming that a grader's reliability follows a Gamma distribution with the shape parameter equal to the grader's own grade. The PG_6 model is an extension of this model [6].

PG_7	1.24	0.02	1.45	0.01	1.31	0.01

- PG_5 : This is a probabilistic model assuming that a grader’s reliability follows a Gaussian distribution with the mean equal to the grader’s own grade. The PG_7 model is an extension of this model.

5.3 Experimental Settings

As described before, many hyper-parameters are used in the proposed models and baselines, and it is important to set reasonable values for these hyper-parameters. In this section, we describe how to set the values of these hyper-parameters in our experiment.

Since the proposed models are the extensions of the PG_4 and PG_5 model in [6], to evaluate the effect of leveraging relative grades, we set the same values for the shared hyper-parameters in the proposed models and the PG_4 and PG_5 models. We use the mean and variance of the peer grades as the mean (μ) and variance ($\frac{1}{\gamma}$) of the prior distribution of the true grade (s_i). As claimed in [6], the β in the PG_4 model which decides the rate of the Gamma distribution for the grader’s reliability and the λ in the PG_5 model which determines the variance of the Gaussian distribution for peer grades are the most important hyper-parameters. These parameters have a significant influence on the performance of these two models while other hyper-parameters influence the performance slightly if set in a reasonable range. Thus we mainly tune β in the PG_4 and PG_6 model and λ in the PG_5 and PG_7 model. We search for these two hyper-parameters in the range of [50, 300] with the interval of 50 to get the best performance. We set η to 0.1 in our experiment, and in the PG_5 and PG_7 model, β is set to 0.1. For each latent variable, we sample it for 300 iterations and the first 60 iterations are the burn-in iterations that will be discarded. The average results over 10 runs with the hyper-parameter settings described above are reported.

5.4 Real Dataset Performance

We use Root-Mean-Square-Error (RMSE) to evaluate the performance of the proposed models and baselines on the datasets. The experimental results are shown in Table 3. From Table 3, we can find that on all these three questions, the PG_6 and PG_7 models outperform other baselines. The RMSE of the PG_6 and the PG_7 models which incorporate the relative observed grades to capture the dependency between true grades of submissions has dropped compared with that of the PG_4 and PG_5 models. The results demonstrate the effectiveness of incorporating relative peer grades in cardinal peer grade estimation.

To better illustrate the performance of the PG_6 and PG_7 models, we further compare the estimated grades with the

ground truth on individual submissions in Figure 2. The submissions are sorted with an increasing order of the ground truth. Then we plot the estimated grades from *Mean* (the best naive method), PG_5 (the best baseline), and the proposed PG_7 model which has the best performance. We can find that the estimated grades by all three models show an increasing trend, but *Mean* shows a strong negative bias in the peer grades: the peer grades are consistently lower than the ground truth grade. Therefore, it is important to model the bias in graders to improve the aggregation results. PG_5 and PG_7 both show positive bias compared with the ground truth, but PG_5 ’s bias is a bit higher. The comparison between PG_5 and PG_7 illustrates that the relative grades can also help estimate the bias more accurately. It may imply that although graders cannot give accurate absolute grades, they can assign accurate relative grades.

We further compare the experimental bias estimated by the proposed models with the real bias. The experimental bias is defined as the average difference between the peer grades assigned by a grader and the estimated true grades. The real bias is defined as the average difference between the peer grades assigned by a grader and the ground truth. For example, a grader g grades two submissions from student i and j , the experimental bias of this grader is $\frac{(z_i^g - s_i) + (z_j^g - s_j)}{2}$

and the real bias is $\frac{(z_i^g - s_i^*) + (z_j^g - s_j^*)}{2}$, where s_i and s_j are the estimated grades, s_i^* and s_j^* are the groundtruth grades for submission i and j . The results are illustrated in Figure 3, where x-axis denotes the real bias and y-axis denotes the experimental bias. We can see that most graders are harsh graders whose real biases are less than 0. The diagonal means that the estimated bias is the same as the real bias. The closer to the diagonal, the more accurate the bias estimation is. We can observe that our estimated bias is close to the real bias. With better bias estimation, the proposed models achieve more accurate cardinal estimation. This result again indicates the informativeness of relative grades in estimating final grades.

5.5 Sensitivity of Hyper-parameters

To show how the value of hyper-parameter β in the PG_6 model and the hyper-parameter λ in the PG_7 model will influence the performance, we conduct experiments using different values of these two hyper-parameters with all other hyper-parameter fixed. In the experiment to test the sensitivity of the models, the settings for other fixed hyper-parameters are the same as described above and the β in the PG_6 model and the λ in the PG_7 model are set from 50 to 300 with an interval of 50. The results in Figure 4 show that in a reasonable range these two models are robust to the value of the parameter and achieve acceptable performance.

6. CONCLUSIONS AND FUTURE WORK

With the popularity of the MOOCs, peer assessment has become an effective paradigm for large-scale grading. The aggregation of peer grades is a challenging problem due to the various levels of bias and reliability among graders that are unknown. Existing work contributes to the development of effective peer grading aggregation methods by modeling grader bias and reliability, but they ignore an important aspect in peer grading aggregation, which is the dependency relation among grades. In these models, the relative grades are not considered and the true grades of submission are

Figure 2: The estimated grades of three questions using mean, the PG_6 and PG_7 model and ground truth. The submissions are sorted by their ground truth.

Figure 3: The comparison of experimental bias with real bias

Figure 4: Hyper-parameter sensitivity of the PG_6 and PG_7 model

modeled independently. Modeling the dependencies among the true grades of different submissions can help improve the robustness of the aggregated grade estimation. In this paper, we propose two novel models that leverage relative grades to achieve improved estimation of final grades. In the proposed probabilistic models, we capture the distributions of true scores based on graders' bias and reliability degrees as well as their own submission scores which represents their knowledge about the question. In addition, the proposed models couple the true scores of different submissions via their differences. Effective inference algorithms are proposed to infer both model parameters and final scores. Experimental results demonstrate that the proposed models improve the accuracy of cardinal peer grading estimation. It can also be observed that the relative peer grades among submissions indeed contribute to the improvement in the accuracy of cardinal peer grading estimation.

In the future, we will investigate how to better model the ability of graders reflecting both reliability and bias of graders and how to cluster the graders and submissions into different groups to improve the peer assessment.

ABSTRACT

Computational models of learning can be powerful tools to test educational technologies, automate the authoring of instructional software, and advance theories of learning. These mechanistic models of learning, which instantiate computational theories of the learning process, are capable of making predictions about learners' performance in instructional technologies given only the technology itself without fitting any parameters to existing learners' data. While these so call "zero-parameter" models have been successful in modeling student learning in intelligent tutoring systems they still show systematic deviation from human learning performance. One deviation stems from the computational models' lack of prior knowledge—all models start off as a blank slate—leading to substantial differences in performance at the first practice opportunity. In this paper, we explore three different strategies for accounting for prior knowledge within computational models of learning and the effect of these strategies on the predictive accuracy of these models.

1. INTRODUCTION

A computational theory approach to modeling psychological phenomenon consist of building simulations of cognitive processes and testing their ability to emulate and explain human behavior. Within educational data mining there have been several attempts to model student learning processes using a computational theory approach. For example SimStudent [1] is a computational approach which simulates human students. The Apprentice Learner (AL) Architecture [2] is a modular framework for creating computational agents such as SimStudent that learn to solve problems in intelligent tutoring systems (ITSs) as a human student would. These computational agents mimic the inductive learning process

undergone by students in response to examples and correctness feedback given in a particular domain.

These approaches afford several different use cases relevant to the domain of EDM. First, as cognitive models of human learning, these computational agent models can be used to test theories of human learning. The AL framework uniquely serves this role since it is designed so that its components can be interchanged, to enable the instantiation of different theories of learning that can be tested against human behavior.

Second, insofar as as computational agents constitute high fidelity models of human learning as simulated students, they can be used as cognitive crash dummies for instructional design prior to the longer process of classroom trials and A/B studies. For example, experiments with SimStudent and agents built with AL showed that interleaving fraction addition and fraction multiplication problems would lead to more efficient learning by opportunity in an ITS [14]. This result was later corroborated by human trials [15].

Finally, simulated students can be used as efficient authoring tools. Simulated students can form generalized production rules from examples and correctness feedback meaning that they can be trained in a manner similar to example tracing [3] to build expert models for ITSs. Expert models trained with SimStudent, for example, have similar expressivity and accuracy as hand-written production rule models, but can be built in significantly less time and without any programming knowledge required by the author [12, 11, 16].

Computational theory approaches of learning such as SimStudent and the simulated students built with the AL framework are at their core zero-parameter models of human learning. These approaches are distinct from performance pattern models such as the Additive Factors Model (AFM) [4, 5] or Bayesian Knowledge Tracing (BKT) [6] since they attempt to predict the presence of a pattern in behavior (e.g., learning a new skill or misconception) given only the task environment and a few underlying assumptions about the learning process rather than fitting to data from individual students. These computational theory approaches to human

Koedinger "Toward Near Zero-Parameter Prediction Using a Computational Model of Student Learning" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 456 - 461

modeling attempt to make predictions of human behavior without knowing anything about the humans that they are modeling, putting the burden of the modeling process on deliberate and explainable algorithmic design choices. While there are added challenges to designing computational theory approaches that accurately reflect human behavior, they have the advantage of fine-grained explainability. Since a computational theory approach actually performs the tasks given to the students that it attempts to model, the fidelity of the model to its human counterparts can be evaluated in a more incisive manner, considering not just the performance of the model by opportunity, but the types of errors it makes and strategies it employs as well.

While computational theory models have demonstrated some success in the past they still possess several systematic issues in their performance. When applied to the task of modeling learning many computational theory models manifest some version of a cold start problem. Namely, as these models, by definition, are not fit to information from individual students, they often lack the ability to account for individual differences in prior knowledge or experience that students bring to bear. Performance pattern models are free to deal with this problem in a number of ways. For example, AFM and its variants often fit some kind of student intercept to allow for variation among students' initial ability [4, 5]. Several strategies for estimating Bayesian priors in BKT have been proposed in the EDM literature [6, 7]. In a performance pattern context estimating prior knowledge amounts to estimating some parameter between 0 and 1. Computational theory models, on the other hand, require a fully specified mechanistic skill to be initialized and refined in a learning process that directly models the process of a human trying to master skills in an intelligent tutoring system.

In this paper we explore several strategies for accounting for prior knowledge in the AL architecture and compare each strategy's ability to generate learner performance similar to that of students. We close with a discussion of these strategies and discuss the limitations of our current approaches as well as directions for future work.

2. OUR EXPERIMENT

2.1 The Apprentice Learner Architecture

The Apprentice Learner (AL) Architecture is a modular framework for modeling the human learning process from demonstrations and feedback [2]. The purpose of the architecture is to serve as a test-bed for computational theory approaches to student modeling. Agents created in the AL framework induce production rules from training that can be provided either interactively by a human or by working with an existing ITS. In our experiments we use the latter approach to train a set of simulated students on an intelligent tutoring system with the same order of problems as each student from a human dataset.

AL agents receive two types of feedback from ITSs, examples and correctness feedback. When an AL agent has a learned production rule that can fire it will try the resulting action and get correctness feedback from the ITS, otherwise the agent will request a hint (i.e., an example) from the ITS. Through positive examples from hint requests and positive feedback, and negative examples from negative feed-

back, AL refines its understanding of the domain and learns to correctly solve problems in the ITS.

To induce a production rule model suitable for solving problems, AL employs a four mechanism learning process consisting of *when-learning*, *where-learning*, *how-learning*, and *which-learning*. The *when-* and *where-learning* mechanisms determine the context in which a production rule should fire, the *how-learning* mechanism searches for chains of overly general operators that explain tutor demonstrations to determine what a production should do when it fires, and the *which-learning* determines which production rule should fire if multiple are applicable.

The operators that *how-learning* employs are "overly general", in the sense that they are applicable in a wide range of domains, but not specific enough to solve problems in any particular domain. Overly general operators do not constitute production rules since they are not programmed with any sense of when they should fire. In our experiments we use one perceptual operator 'equals' which adds to the problem state the fact that two values are equal, and four procedural operators 'add', 'subtract', 'multiply' and 'divide'. The conditions in which these operators should be utilized, the particular interface elements from which they derive their numerical inputs, and the interface elements that will receive their outputs are learned by the *when-* and *where-learning* mechanisms respectively to create full production rules.

The AL agents in our experiments employ Trestle [13], an incremental hierarchical categorization algorithm for *when-learning*. For *where-learning*, since we use only static interfaces in our experiments, we employed a 'most specific' strategy, which uses the inputs and outputs present in positive training examples without trying to generalize from those examples to unseen cases. We allow our *how-learning* mechanism to only use single operation explanations (i.e. just multiply or add two numbers, not three numbers or combinations of operators). The *which-learning* mechanism chooses the production rule which has been employed successfully with the highest frequency so far given the current state representation.

2.2 Data Source

To evaluate different methods of pretraining AL agents we used student performance data from an ITS for fraction arithmetic [15]. The dataset consisted of the work of 117 students on three different types of fraction arithmetic problems: 1) adding fractions with the same denominator, 2) adding fractions with different denominators, and 3) multiplying fractions. In the interface students are first asked if they need to convert the two fractions, which is false in the addition-same and multiplication cases and true in the addition-different case. If the fractions need to be converted then the students must find the common denominator between them and write in the converted fractions before adding them. This dataset is available on DataShop [9]¹.

¹<https://pslcdatashop.web.cmu.edu/Project?id=243>

2.3 Training Strategies

We explored three different strategies for accounting for prior knowledge in AL Agents. For each of these strategies an agent was paired with a human student and provided some form of pretraining based on data collected about that student prior to working through that student's problem sequence in the data. In our experiments we attempted three different strategies to account for prior knowledge estimated fraction prior experience, estimated whole number prior experience, and demonstrated pretest. Additionally, we ran a no pretraining control condition which begins from a conventional cold start.

2.3.1 Estimating Prior Experience

In the estimated fraction and estimated whole number prior experience strategies agents worked through a number of pretraining problems based on estimates of each student's prior opportunities to practice problems in each of the three types of fraction arithmetic problem. We estimated the number of prior opportunities (P_{ik}) that a student i had on each knowledge component (KC) k [10] in the fraction arithmetic tutor. Taking the AFM mixed model regression equation:

$$\log\left(\frac{p_{ij}}{1-p_{ij}}\right) = \theta_i + \sum_k (q_{jk}\beta_k + q_{jk}\gamma_k T_{ik}), \theta_i \sim \mathcal{N}(0, \sigma^2)$$

Consider an imaginary tabula-rasa student with no knowledge of anything at all with student intercept $\theta_{-\infty}$, and a student with student-intercept θ . We can find the number of prior opportunities P_{ik} such that the tabula-rasa student has the same log odds of answering a question in KC k as student i :

$$\begin{aligned} \theta_{-\infty} + \sum_k (q_{jk}\beta_k) + \sum_k (q_{jk}\gamma_k P_{ik}) &= \theta_i + \sum_k (q_{jk}\beta_k) \\ \Rightarrow P_{ik} &= \frac{\theta_i - \theta_{-\infty}}{\gamma_k} \end{aligned}$$

An issue with this formulation is that a true tabula-rasa student would have $\theta_{-\infty}$ equal to $-\infty$, so we introduce an approximation for $\theta_{-\infty}$ in order to get reasonable values for P_{ik} . In our experiments we choose $\theta_{-\infty} = -2$ since this is the student intercept at which a student practicing a single KC step with a KC intercept of zero would have about a 10% probability of getting the step correct. Although this an arbitrary choice, we believe it is a reasonable one, much in the same way that it is reasonable to choose a 90% chance of correct behavior as a mastery threshold in a BKT model.

There are three distinct types of fraction arithmetic problems, which each have their own sets of KCs. In the case of fraction addition the two fractions can either have the same denominator, in which case the student need only add the numerators, or the denominators could be different, requiring the student to convert the fractions before adding. In the third case, fraction multiplication, the KCs are distinct from the addition cases. Since in practice fraction arithmetic problems are not presented with any of their KCs in isolation we estimated the number of problems of each type to give as prior training to our learning agents as the minimum P_{ik} among the problems of a given type. For the

estimated fraction prior experience case we pretrain on a number of random problems from each type according to these estimates. In the estimated whole number prior experience case we pretrain as many random whole number addition problems as there are estimated same denominator problems and as many random whole number multiplication problems as estimated multiplication problems.

In the estimated fraction condition, randomly generated problems were restricted to have denominators between 2 and 12 with numerators less than each fraction's denominator (i.e., no improper fractions). In the estimated whole number condition, each agent was given randomly generated whole number arithmetic problems prior to beginning the core tutoring sequence. These whole number arithmetic tutors were restricted to numbers between 1 and 12.

2.3.2 Demonstrating Prior Answers

In the demonstrated pretest case we pretrain the AL agents by providing them with demonstrations of the exact answers that students gave in a pretest evaluation of the original study. In order to model both the knowledge and misconceptions of the student, these answers are given to AL as positive examples regardless of whether or not each of the students' answers were correct. The goal here is that the pretest encapsulates a picture of each students' prior conceptions that may contain more information than a fit parameter. The pretest is a snapshot of students behavior under a particular set of problems, a sample which we use to infuse an associated AL agent with the same knowledge and misconceptions as the original student.

One limitation of our pretest demonstration approach is that the available pretest data only contained the given fraction problems and the students' final answers. Thus, the demonstrations that we provided to the agents appeared as single steps even though the human students may have done multiple mental calculations to arrive at their answer. This issue is likely to be particularly salient on fraction addition problems with different denominators as the common denominator process would not be apparent.

3. RESULTS

In Figure 1 we see that the estimated fraction condition gets closest to the human first opportunity performance, followed by the demonstrated pretest condition. The estimated whole number condition behaves almost equivalent to the control case with a 100% first opportunity error rate.

To test the fit of each strategy to the human data we calculate the residuals between the human learning curves and the learning curves generated from the AL agents run with each pretraining strategy (Figure 2). Table 1 shows several statistics of the fit of each strategy to the human data. The "Accuracy" column shows the mean accuracy between the correctness (0 for incorrect and 1 for correct) of each human and that human's AL agent counterpart over all students and opportunities. The "First Opp. Accuracy" column shows this same statistic, but only for the first opportunity. In both cases the estimated fraction strategy shows the best fit to the human data.

In addition to testing the predictive accuracy of the models,

Figure 1: Learning curves aggregated over all knowledge components for each pertaining strategy and the human learning curves.

Figure 2: Learning curve residuals (human minus agent) for each strategy across all knowledge components. Error bars are standard errors.

we next looked at the explanatory power of the model— by looking at its ability to account for variation in the human error rates over the course of problem solving. As a coarse measure of explanatory power, we first conducted a χ^2 test of independence between each model correctness and the human correctness. This test confirmed that there is a significant relationship between each models’ predictions and the human correctness (independence hypothesis rejected for all models, $p < 0.001$). Next, we looked to more finely evaluate how well each model explains variation in the human data. To do this we used a mixed-effects regression analysis [16]. For this analysis, we used a mixed-effects model with fixed effects for each model prediction as well as the practice opportunity counts. The model also included random effects for the intercept and slopes of each knowledge components as well as intercepts for each student.² This model,

²The mixed-effect regression model used in R: $\text{Human.Correctness} \sim \text{Agent.Correctness} + \text{Opportunity} + (1$

which is effectively the Additive Factors Model [4, 5] with an additional term for the model predictions, serves a role similar to a repeated measures ANOVA analysis by accounting for general effects of within student and skill (knowledge component) performance as well as the effect of repeated practice. The model enabled us to evaluate how well each computational models’ predictions improved the overall regression model fit over the baseline AFM model. By applying model fit statistics, such as AIC, to these mixed-effects models, we could evaluate which model better accounted for variation in the human behavior above general practice effects and general correlations of behavior within students and skills. The baseline AFM model fit to this data had an AIC score of 9558.7. The “AIC” column in Table 1 shows the AIC scores for the mixed-effects model with the added fixed effects for each respective computational model. Note, the numbers of free parameters and data points between each of these models is equivalent thus we did not consider other fit statistics such as BIC or HQC as they would have resulted in an identical ordering.

These results show that all models provide some explanatory power over the baseline AFM model. However, the no pretraining control model appears to provide the most explanatory power. Although this result seems counter-intuitive from the graphs shown in Figure 1, there is at least one possible explanation. Mainly, that the estimated fraction model better fits the average of all students whereas the no pretraining model better fits individual students—specifically students with high initial error. The estimated fraction model likely better fits the students that perform better initially; however these students have less variation in their behavior that the model might account for and this variation is already accounted for as a general within-student effect of the regression evaluation. In contrast, the no pretraining control and demonstrated pretest models better fit students with lower performance at the beginning, who also have more variation to account for.

Finally, we analyzed the residuals shown in Figure 2 using a linear regression analysis. This analysis fit a line to each residual curve to get an estimate of the intercept and slope of these curves. Table 2 shows the slopes and intercepts of these linear models with their accompanying 95% confidence regions. This analysis shows there is a significant intercept and slope for each of the models (all intercepts and slopes are non-zero, $p < 0.001$). However, the estimated fraction model has the intercepts and slopes that are closest to zero, suggesting that it is a better fit of the overall error rates and error rates by opportunity.

+ Opportunity | KnowledgeComponent) + (1 | Student.Id).

4. DISCUSSION

Our current experiments in accounting for prior knowledge in AL agents have mixed results, but yield fruitful directions for future work. Our most promising method, the estimated fraction prior experience case, reduces the average first opportunity error rate across all knowledge components down to about 40%. The human students by contrast begin at about a 30% error rate. The demonstrated pretest case yielded little improvement over the control. The only slight first opportunity improvement in the demonstrated pretest case is likely due to the often erroneous answers that the students produced in the pretest, which we presented to our AL agents as the ground truth in this condition. Our original hypothesis was that these erroneous but positively labelled examples would account for any existing misconceptions in the human students. However, these erroneous examples may have gone too far toward confusing the AL agents. An alternate explanation is that the lack of negative examples in this case hinders the AL agents' capacity to effectively delineate between their learned production rules. Finally, since the estimated whole number learning curves turned out to behave equivalently to the control case both in first opportunity error rate and in over-all shape, we need to look more closely at AL's capabilities for cross-interface skill transfer in future work.

We consider these experiments to be a first exploratory pass at accounting for prior knowledge in computational modeling approaches to human learning. Among them, the estimated fraction prior experience case is decidedly the closest to human behavior. However, we certainly think we can get much closer to the human behavior going forward.

One direction for future work is to improve our estimates for the number of opportunities to pre-train our agents with to account for the prior knowledge of their human counterparts so that the intercepts of the human and AL agent learning curves match. We can approximate the average of the ground truth number of prior opportunities by calculating the number of opportunities that the control condition takes to gain parity with the human students at their first opportunity. By comparison to this ground truth average it appears that our estimates are too large in the multiplication (14.17 vs. 6) and same denominator addition problems (6.76 vs. 4) and too low in the addition different problems (6.79 vs. 9). We found that these discrepancies could not be remedied by a different choice of $\theta_{-\infty}$.

In previous evaluations of the AL framework in other domains AL agents learned more per opportunity than the human subjects [16]. We hope to explore this fact further by evaluating situations where AL agents over/under performs relative to the humans, and find ways of correcting the discrepancy.

Table 2: Linear model fit to residuals.

Strategy	Intercept	Slope
No Pretraining	-0.474 ± 0.012	0.030 ± 0.002

Demo Pretest	-0.422 ± 0.012	0.026 ± 0.001
Est. Whole Num	-0.490 ± 0.012	0.031 ± 0.001

One direction for future work that will help us converge on an accurate model of a human learning, is to give AL agents the capability to make random guesses guided by statistics of human errors. This behavior might include inputting common random numbers, copying random numbers, and applying overly general operators at random. Much in the same way that we have estimated the P_{ik} from human data, we would need to estimate a distribution from which these behaviors could be drawn. Similar statistics could be estimated for inferential and procedural slip mistakes³.

The question certainly is raised: if we must rely on descriptors of human behavior derived from fitting statistical models to human performance, then to what extent are we employing a zero-parameter approach to modeling? No doubt, we are using fit parameters in our modeling approach by bootstrapping our models guided by student intercepts calculated from AFM. However, our computational modelling approach attempts to replicate human behavior instead of only fitting performance, and this process is guided a priori via computational theories of student learning, not by comparison to human data.

Although our nearly zero-parameter computational approach opens up many possibilities for testing theories of human learning, it comes with its own set of difficulties and limitations. In contrast to performance estimation models such as AFM and BKT which require only the logs of human performance on an ITS, our approach also requires a working ITS for the AL agent to work against. This limits the applicability of our method to older datasets for which the actual tutoring interfaces have been lost to time. Currently our system works on the newest HTML version of CTAT and has been used successfully in previous experiments on the older Java version of CTAT as well. However, in order to use different ITSs new code must be written to communicate tutor events to the AL framework's RESTful API.

While a nearly zero-parameter computational approach to human learning allows us to form and test theories of learning in a very detailed manner, it should be noted that the strength of any claim about the underlying cognitive processes of students is dependant on both the specificity of such a model in replicating human behavior and the generalizability of such a model across different domains. Here we have looked at just a single domain, fraction arithmetic, since it is amenable to all three of our proposed strategies. However, it should be noted that although validity claims are strengthened in a zero-parameter computational approach by the fact that behavior must be explained on an algorithmic level and not by fitting parameters, it is still possible that two underlying learning mechanisms yield almost indistinguishable behavior. Thus generalizability is essential to any claim about human cognitive processes. However, generalizability cannot be gained for free by the availability of more diverse data, as is often the case with deep learning models. Rather, any observed discrepancies between domains must be explicitly explained and accounted for by the investigator at an algorithmic level. This fact lends very high explainability to a zero-parameter computational approach, but nonetheless presents an added challenge.

³These statistics would be difficult to estimate convincingly with a zero-parameter approach.

5. CONCLUSION

We have tested three different strategies for accounting for prior knowledge in AL agents trained on fraction arithmetic problems. Our three strategies were 1) 'estimated fraction prior experience' where we gave the AL agents additional practice in fraction arithmetic problems before starting the core tutor problems, 2) 'demonstrated pretest' where we showed the AL agents their human counterparts' answers on pretest problems before starting the core tutor problems, and 3) 'estimated whole number prior experience' where we pretrained the AL agents with whole number arithmetic problems. Our results showed that in terms of matching human learning curves the estimated fraction case beats out all the other strategies. However the control case, which had no pretraining at all, best explains the variance in the data.

We have discussed several limitations of our nearly zero-parameter computational approach to testing theories of learning, and have offered several avenues for improvement. Concerning the limited accuracy of our current approach in estimating the number of prior opportunities necessary for an AL agent to account for the prior knowledge of its human counterpart, we have offered an avenue for further refinement. Additionally we have discussed ways that we might accounting for non-deterministic human behavior such as initial guessing. Finally, we have addressed the zero-parameter nature of our approach and considered its technical and epistemological limitations and strengths. We consider the AL framework to be a strong avenue for testing theories of learning, and hope to refine our computational approach to modeling human learning in future work.

ABSTRACT

We explored¹ how learners' *subjective ratings* of open educational resources (OERs) in terms of how much they find them "helpful" can predict the actual *learning gains* associated with those resources as measured with pre- and post-tests. To this end, we developed a probabilistic model called GRAM (Gaussian Rating Aggregation Model) that combines subjective ratings from multiple learners into an aggregate quality score of each resource. Based on an experiment we conducted on Mechanical Turk ($n = 304$ participants with $m = 17$ math tutorial videos as resources), we found that aggregated subjective ratings are highly (and stat. sig.) predictive of the resources' average learning gains, with Pearson correlation of 0.78. Moreover, when predicting average learning gains of *new* learners, subjective scores were still predictive (Pearson correlation of 0.49) and attained higher prediction accuracy than a model that directly uses pre- and post-test data to estimate learning gains for each resource. These results have potential implications for large-scale learning platforms (e.g., MOOCs, Khan Academy) that assign resources (tutorials, explanations, hints, etc.) to learners based on the expected learning gains.

Keywords

open educational resources (OER); adaptive learning; crowdsourcing; treatment effect estimation

1. INTRODUCTION

Consider a hypothetical large-scale online learning platform in which learners engage with open educational resources (OERs) that are sampled from a vast collection. These resources could include tutorial videos, practice exercises, explanations of wrong answers, hints, etc. In order to help students learn optimally, the learning platform must decide

¹The data and source code (in R) to reproduce the results in this paper are available at <https://github.com/jwhitehill/gram>.

Jacob Whitehill, Cecilia Aguerrebere and Benjamin Hylak "Do Learners Know What's Good for Them? Crowdsourcing Subjective Ratings of OERs to Predict Learning Gains" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 462 - 467

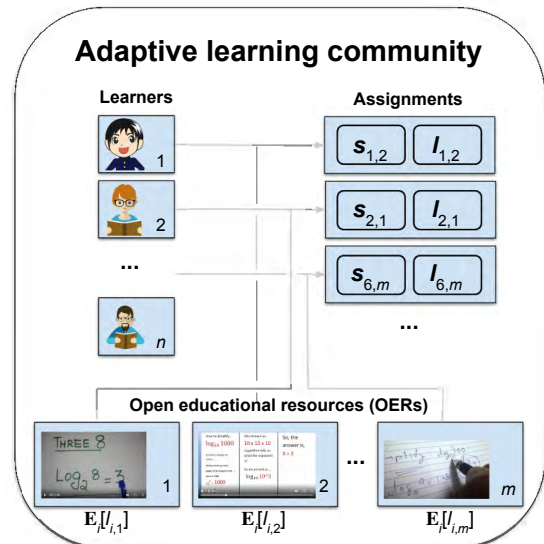

Figure 1: An adaptive learning community in which each learner i is assigned different resources over time, and the effectiveness (expected learning gains l_{ij}) of each resource j is estimated both from test scores as well as from *subjective ratings* s_{ij} given by the learners. Gray lines show hypothetical assignments of OERs to learners. $E_i[l_{ij}]$ denotes the average learning gains over all learners i who received j .

which resource is most beneficial to each learner at each moment in time, and then assign that resource to the learner (see Figure 1). Although various criteria could be used for this decision (e.g., the impact on student engagement), perhaps the most natural one is how much the student will learn – *learning gains* – from receiving the resource.

The standard way to estimate the *learning gains* l_{ij} of each resource is to give each student i who receives resource j a pre-test (before receiving it) and post-test (after receiving it) to measure how much she/he learned, i.e., the difference between pre- and post-tests. We call each (learner, resource)-pair an *assignment*. After a sufficient number of assignments, the average learning gains of each resource $E_i[l_{ij}]$ (averaged over all learners i who receive j) can be estimated. Then, using these estimates for all the resources, the most effective ones can be served to students. Unfortunately, this approach to estimating the quality of a large collection of

OERs is expensive because testing takes a long time. On the other hand, after receiving a resource j , learners may have a *subjective opinion* about how effective j was. These opinions can arguably be queried more easily and efficiently than administering tests; for example, the learner could simply select between 1 and 5 stars (à la Yelp) to express how much she/he liked it. It is even possible that subjective scores might be better than test scores in some situations. For example, even if a learner her/himself has already mastered a skill and thus has a learning gain of 0, she/he might still be able to *judge* whether a resource is useful.

When using subjective scores to predict learning gains, care must be taken: some learners may be more or less reliable in making such judgments. However, there are reasons to be optimistic: (1) As long as enough learners “vote”, then the noise of their judgments can be averaged out. (2) Using algorithms for crowdsourcing consensus (see below), the reliabilities of the learners as well as the learning gains of the resources can be estimated in an unsupervised fashion. The **chief contribution** of our work is to propose and evaluate experimentally an efficient crowdsourcing model to estimate the quality of a set of learning resources by combining multiple learners’ subjective opinions about them.

2. RELATED WORK

Students’ judgments of learning and teaching: Estimating the learning gains of an OER is related to metacognition. The ability of students to judge how well *other* people learn has been analyzed experimentally in prior works such as [12, 3]. However, we are not aware of previous research that considers this problem in the large scale of an online learning community or how to combine multiple learners’ judgments to improve accuracy. In the context of student course evaluations, there is evidence that learners may actually be poor judges of their teachers’ effectiveness [7, 4].

Adaptive online learning communities: Adaptive learning communities that decide which resources to serve to students based on up-to-date estimates have generated recent interest in the educational data mining and reinforcement learning communities. Notable works are by Rafferty, et al. [9] and Williams, et al. [17]. In these works, reinforcement learning techniques based on bandits and Thompson sampling were used both to estimate the learning gains of each resource and simultaneously to assign resources to learners. Our work is complementary: we explore how not only test score information, but subjective ratings provided by learners, could be useful in estimating the utility of each resource.

Crowdsourcing for education: In [14], Weld et al. provided an overview of how online learning creates challenges due to its large scale, but also suggests possible ways in which crowdsourcing can offer solutions to these challenges. Heffernan, et al. [6] proposes a vision of how crowdsourcing can help provide important functionality toward adaptive personalized online learning. As one specific instance of how the crowd can contribute new resources to an online learning community, Williams, et al. showed that people on Mechanical Turk can be induced to author novel and useful text-based explanations [17]. Whitehill & Seltzer [16] showed that Mechanical Turk workers can even create entire tutorial videos, at least some of which are effective at help-

Figure 2: Gaussian Rating Aggregation Model (GRAM). Only the subjective ratings s_{ij} from student i about resource j are observed. Latent variable q_j expresses the “quality” of resource j and is used to predict the learning gains of students who receive the resource.

ing students to learn. Peer grading (e.g., Piech, et al. [8]) and peer feedback are other ways of harnessing the crowd to provide useful feedback for learners at scale.

Crowdsourcing consensus algorithms: Since Dawid and Skene’s seminal work [5] on optimal weighting of annotators’ opinions, there have been a slew (e.g., [15, 10, 11, 2, 13, 1]) of crowdsourcing models, which are suitable for different kinds of tasks (binary, multiple choice, etc.) and capture different features of the labeling task (e.g., task difficulty, biases).

3. GAUSSIAN RATING AGGREGATION MODEL (GRAM)

We model the *quality* of each open educational resource (OER) j with a real number, q_j , that can be estimated by aggregating over many (real-valued) *subjective ratings* s_{ij} from many learners i . We thus develop a Gaussian probability model of how each s_{ij} is related to each q_j as well as several parameters specific to each learner i . The model is portrayed in Figure 2: Let μ_i and γ_i^2 be the bias and reliability (variance) of learner i , respectively. Let q_j be the ground-truth quality of resource j . We posit that student i ’s label s_{ij} for resource j is a Gaussian random variable with mean $q_j + \mu_i$ and variance γ_i^2 . In other words, if the ground-truth quality is q_j , then student i adds a bias μ_i , and then adds independent 0-mean Gaussian noise with variance γ_i^2 . We can express these relationships using the conditional probability density function (PDF) $P(s_{ij} | q_j, \mu_i, \gamma_i^2) = \mathcal{N}(q_j + \mu_i, \gamma_i^2)$ where \mathcal{N} is a Gaussian with a given mean and variance.

3.1 Inference

As with many crowdsourcing consensus models, inference in the GRAM requires solving a “chicken-and-the-egg” problem: if the parameters μ_i, γ_i^2 of each learner i were known, then an optimal weighting of their votes s_{ij} could be used to estimate the quality q_j of each resource j . On the other hand, if the ground-truth quality q_j of each resource were known, then the parameters of each learner could be estimated. We solve this problem using Expectation-Maximization: in the E-Step we compute the PDF of each q_j conditional on the parameters $\{\mu_i, \gamma_i\}$. In the M-Step, we compute the expected joint log-likelihood of the $\{q_j\}$ and $\{s_{ij}\}$ w.r.t. the PDFs computed during the previous E-Step, and then maximize this expectation w.r.t. the parameters $\{\mu_i, \gamma_i\}$. Since the GRAM is Gaussian, both the E- and M-Steps can be done analytically, and thus the algorithm is very efficient.

Let the mean and variance of the prior distribution over each q_j be \bar{m} and \bar{s}^2 , respectively. Recall that the product of two Gaussian PDFs, with means m_1 and m_2 and variances s_1^2 and s_2^2 , respectively, is also Gaussian and has a mean $s^2(m_1/s_1^2 + m_2/s_2^2)$ and variance $s^2 = (1/s_1^2 + 1/s_2^2)^{-1}$.

E-Step:

$$\begin{aligned}
\tilde{P}(q_j) &\doteq P(q_j \mid \{s_{ij}\}, \{\mu_i\}, \{\gamma_i^2\}) \\
&\propto P(q_j \mid \{\mu_i\}, \{\gamma_i^2\}) P(\{s_{ij}\} \mid q_j, \{\mu_i\}, \{\gamma_i^2\}) \\
&= P(q_j) \prod_i P(s_{ij} \mid q_j, \mu_i, \gamma_i^2) \\
&= \mathcal{N}(m_j, s_j^2) \quad \text{where} \\
s_j^2 &= \left(1/\bar{s}^2 + \sum_i 1/\gamma_i^2\right)^{-1} \\
m_j &= s_j^2 \left(\bar{m}/\bar{s}^2 + \sum_i (s_{ij} - \mu_i)/\gamma_i^2\right)
\end{aligned}$$

In other words, the posterior distribution of each q_j is a Gaussian whose mean is the average of the relevant s_{ij} after shifting each one by the learner's bias μ_i and then scaling it by γ_i^2 . We can achieve a non-informative prior by setting the variance \bar{s}^2 to be very high (e.g., 1000).

M-Step: We derive the auxiliary function Q as the expectation, w.r.t. the PDF \tilde{P} computed during the E-Step, of the joint log-likelihood of the observed ratings $\{s_{ij}\}$ and hidden ratings $\{q_j\}$. In the derivation below, C and D are constants that do not depend on any of the parameters.

$$\begin{aligned}
Q(\{\mu_i\}, \{\gamma_i^2\}) &= \mathbb{E} [\log P(\{s_{ij}\}, \{q_j\} \mid \{\mu_i\}, \{\gamma_i^2\})] \\
&= \mathbb{E} \left[\log \prod_j P(q_j \mid \{\mu_i\}, \{\gamma_i^2\}) + \right. \\
&\quad \left. \log \prod_{ij} P(s_{ij} \mid \{q_j\}, \{\mu_i\}, \{\gamma_i^2\}) \right] \\
&= \mathbb{E} \left[\log \prod_j P(q_j) + \log \prod_{ij} P(s_{ij} \mid q_j, \mu_i, \gamma_i^2) \right] \\
&= \sum_j \mathbb{E} [\log P(q_j)] + \sum_{ij} \mathbb{E} [\log P(s_{ij} \mid q_j, \mu_i, \gamma_i^2)] \\
&= \sum_{ij} \int_{-\infty}^{+\infty} dq_j \tilde{P}(q_j) [\log P(s_{ij} \mid q_j, \mu_i, \gamma_i^2)] + C \\
&= - \sum_{ij} \int_{-\infty}^{+\infty} dq_j \tilde{P}(q_j) \left[\frac{(s_{ij} - q_j - \mu_i)^2}{2\gamma_i^2} + \log \gamma_i \right] + D \\
&= - \sum_i \log \gamma_i - \\
&\quad \frac{1}{2} \sum_{ij} \int_{-\infty}^{+\infty} dq_j \tilde{P}(q_j) [(s_{ij} - q_j - \mu_i)^2 / \gamma_i^2] + D \\
&= - \sum_i \log \gamma_i - \frac{1}{2} \sum_{ij} [(s_{ij} - \mu_i)^2 / \gamma_i^2 - \\
&\quad \frac{2(s_{ij} - \mu_i)}{\gamma_i^2} \int_{-\infty}^{+\infty} dq_j \tilde{P}(q_j) q_j + \frac{1}{\gamma_i^2} \int_{-\infty}^{+\infty} dq_j \tilde{P}(q_j) q_j^2]
\end{aligned}$$

where we omitted the constant D in the last line for brevity. The two integrals are the first and second plain moments of $\tilde{P}(q_j)$. The first is the mean of $\tilde{P}(q_j)$, i.e., m_j . The second can be obtained using the fact that the variance $\mathbb{V}[x] = \mathbb{E}[x^2] - \mathbb{E}[x]^2$ for any random variable x . The second plain moment is thus $m_j^2 + s_j^2$. Hence,

$$\begin{aligned}
Q(\{\mu_i\}, \{\gamma_i^2\}) &= - \sum_i \log \gamma_i - \\
&\quad \frac{1}{2} \sum_{ij} \frac{1}{\gamma_i^2} [(s_{ij} - \mu_i)^2 - 2(s_{ij} - \mu_i)m_j + m_j^2 + s_j^2]
\end{aligned}$$

We now differentiate with respect to each parameter, set to 0, and solve:

$$\begin{aligned}
\frac{\partial Q}{\partial \mu_i} &= -\frac{1}{2} \frac{1}{\gamma_i^2} \sum_j (-2(s_{ij} - \mu_i) + 2m_j) \\
0 &= -\frac{1}{\gamma_i^2} \sum_j (\mu_i - s_{ij} + m_j) \\
\sum_j \mu_i &= \sum_j (s_{ij} - m_j) \\
\mu_i &= \frac{1}{N_i} \sum_j (s_{ij} - m_j) \quad \text{where} \\
N_i &\text{ is the \# of ratings from person } i \\
\frac{\partial Q}{\partial \gamma_i} &= -1/\gamma_i + \\
&\quad \frac{1}{\gamma_i^3} \sum_j [(s_{ij} - \mu_i)^2 - 2(s_{ij} - \mu_i)m_j + m_j^2 + s_j^2] \\
\gamma_i^2 &= \sum_j [(s_{ij} - \mu_i)^2 - 2(s_{ij} - \mu_i)m_j + m_j^2 + s_j^2] \quad (2)
\end{aligned}$$

For our experiments we conducted 50 EM iterations.

3.2 Regularizing the model

In the full-fledged GRAM, all of the parameters (bias and reliability of each rater) are learned in an unsupervised fashion (see Section 3.1). Given enough data, these parameters can lead to more accurate estimates of each q_j . However, given limited data, it can also be useful to regularize the model by removing parameters and/or fixing them to known values. In fact, if there are too few subjective scores s_{ij} per learner, then it is important to remove some parameters because otherwise the model encounters identifiability problems. Hence, we considered several variants of the GRAM: (1) each γ_i^2 is estimated, but each μ_i is fixed to 0; (2) each μ_i is estimated, but $\gamma_i^2 = 1$. Finally, we also explored the hypothesis that the students with the higher pre-test scores might, perhaps due to a higher overall engagement, also be more reliable in giving subjective ratings. Hence, we also tried: (4) μ_i is estimated, but $\gamma_i^2 = 1/\sqrt{\mathbb{E}_j[p_{ij}] + \epsilon}$, where $\mathbb{E}_j[p_{ij}]$ is the average (over all their assignments) pre-test score p_{ij} of student i before receiving resource j , and $\epsilon = 0.1$ ensures that the denominator is positive.

4. MODELS FOR COMPARISON

We compared the GRAM to two other models: (1) unweighted average of subjective scores, and (2) prediction model trained directly on pre- and post-test scores.

4.1 Unweighted average of subjective scores

Instead of using the GRAM, we can estimate the quality q_j of each resource j simply as the unweighted average, over all learners who rated j , of their subjective rating scores s_{ij} .

4.2 Average post-test minus pre-test scores

The primary goal of our paper is to assess to what extent subjective scores can estimate the learning gains as measured in a pre-test/post-test paradigm. Hence, a strong baseline – indeed, a likely upper bound – to which to compare our GRAM approach is using a prediction model that *directly* uses test scores (on training data) to estimate students’ learning gains (on testing data). In particular, for each resource j , we estimate $\mathbb{E}_i[l_{ij}]$ – the average difference between post-tests and pre-tests of all students i in the training set who received resource j . We then use this number to predict the average learning gains of resource j in the test set. Obviously, this requires that the adaptive learning system administer pre- and post-tests to learners in order to assess each resource’s quality, and this can be much more time-consuming than simply asking the learner how much she/he likes it. Note that we also considered a prediction model that additionally uses students’ pre-test scores as a co-variate, which could model possible ceiling effects in the tests. However, our results with that model were slightly worse, and hence we do not report them.

5. EXPERIMENT

To assess how well subjective scores of the resources’ quality predicted their associated learning gains, we conducted a randomized experiment on Mechanical Turk. Each participant was paid \$1 and could complete up to 3 tasks. In each task, the pre- and post-tests were the same, but the learning resource was usually different due to random assignment.

5.1 Overview

During the task, participants learned about logarithms. Logarithms are a topic that many adults have learned, but many have forgotten. The topic is hard enough to induce variability in test scores, but easy enough to be learned (or refreshed) in a short amount of time. The learning resources in our experiment comprised a set of tutorial videos on logarithms, most of which were 2-3 minutes long. These resources were authored by different people around the world and collected in a study by Whitehill & Seltzer [16]. Each tutorial explains the solution to one of the math problems that appeared on the pre-test (see Figure 4).

To select videos for our experiment, we watched over 100 candidate tutorial videos collected by [16]. Each video was watched by at least one of the investigators and labeled as either “High Quality,” “Low Quality,” or “Not Acceptable.” Videos labeled as “Not Acceptable” were excluded. To induce some variability in the quality of videos, we chose one “High Quality” video as well as one “Low Quality” for each of the Basic Logarithm problems in the pre-test (see Figure 4), except for a few problems where only one quality level was available. In total, there were $m = 17$ resources (tutorials) that could be assigned; see Figure 3 for examples.

5.2 Protocol

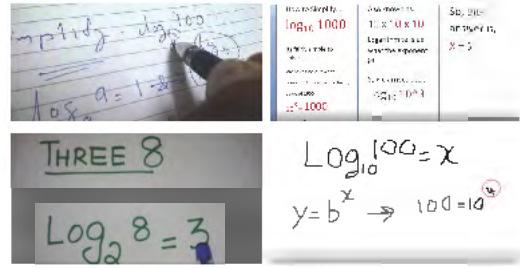

Figure 3: Sample learning resources (tutorial videos on logarithms from [16]) that we used in our experiment.

Basic Logarithms – Simplify:	
$\log_3 1 =$	$\log_9 1 =$
$\log 100 =$	$\log_{\frac{1}{5}} 125 =$
$\log_{10} 1000 =$	$\log_{\frac{1}{x}} x^2 =$
$\log_3 81 =$	$\log_w \frac{1}{w} =$
$\log_2 8 =$	$\log_{\frac{1}{2}} \frac{1}{4} =$
Logarithms and Variables – Simplify:	
$\log_a a^2 =$	$\log_x x^4 =$
$\log_4 4^{2b} =$	$\log_{x-1} (x-1)^y =$
Equations with Logarithms – Solve:	
$\log_3 (x-1) = 4$	$x \log_4 16 = 3$
$z \log_{10} \sqrt{10} = 4$	$y \log_{10} 1000 = 3$

Figure 4: The pre-test on logarithms (borrowed from [16]) in our experiment.

The experiment was built as a web application using HTML and Javascript. Each session consisted of multiple phases:

1. **Survey:** The participants were first asked some basic demographic questions, such as their highest level of education, gender, and age. (Note that we did not use these data in the analyses in this paper.)
2. **Pre-test:** The pre-test surveyed their pre-existing skills in three areas: Basic Logarithms, Logarithms and Variables, and Equations with Logarithms.
3. **Tutorial video:** Participants were then randomly assigned one of the 17 different tutorial videos.
4. **Subjective rating of the resource:** On a Likert scale of 1 to 5, participants were asked how much they agreed with the statement: “This video will help other students learn about logarithms.”
5. **Post-test:** The post-test contained different math problems but was otherwise comparable in format, subject matter, and difficulty to the pre-test.

6. RESULTS AND ANALYSIS

A total of $n = 304$ participants completed the task. Of these, 239 completed 1 task, 35 completed 2 tasks, and 30 completed 3 tasks. Figure 5 shows the box plot, for each resource (tutorial video) j , of the learning gains associated with each resource. There is high variance in learning gains *within* each resource ($\mathbb{E}_j[\mathbb{V}_i[l_{ij}]]$) averaged over the $m = 17$

Figure 5: Box plot, for each OER (math tutorial video) j , of the learning gains l_{ij} for all users i who received it. Resources are sorted according to their median learning gains over all learners who received them.

videos is 0.03) that dwarfs the variance in average learning gains *between* resources ($\mathbb{V}_j[\mathbb{E}_i[l_{ij}]]$ is 0.003), where $\mathbb{V}_i[\cdot]$ denotes the variance with respect to learners i and $\mathbb{V}_j[\cdot]$ denotes the variance with respect to resources j . The relative magnitudes of these variances makes the prediction of average learning gains $\mathbb{E}_i[l_{ij}]$ of each individual resource a challenging task.

6.1 Are subjective ratings correlated with average learning gains?

From the set of all subjective scores collected in our experiment, we can aggregate the ratings s_{ij} , using either the proposed GRAM or simply the unweighted average, for each resource j into a quality estimate q_j . Similarly, we can compute the average learning gains associated with each resource j over all students assigned j to obtain $\mathbb{E}_i[l_{ij}]$, where the subscript indicates that the expectation is w.r.t. all students assigned j . This is equivalent to estimating the *average treatment effect* of resource j . We then compute the correlation (Pearson, Spearman) between these two sets of variables. Note that, since many learners in our experiment completed only one task, we needed to simplify the GRAM in order to avoid identifiability problems (see Section 3.2). Hence, instead of the full-fledged GRAM, we used two variants: one where each $\mu_i = 0$, and one where $\mu_i = 0$ and γ_i^2 is determined by the learner’s pre-test score.

Results are shown in Table 1. Because all correlations are estimated within-sample (i.e., there is no separation of training and validation data), computing the p -values (two-tailed) is straightforward. When the GRAM was used to infer only the reliability γ_i^2 (first line of Table 1), the accuracy is low – 0.15 (Pearson) and 0.13. On the other hand, with the other two GRAM variants, when either a bias μ_i for each learner is learned, the performance was much better – up to 0.78 (Pearson) and 0.75 (Spearman) between the inferred q_j and the average learning gains. These results are easily better than what is obtained using just the unweighted average of the learners’ ratings. Estimating γ_i^2 as a function of each learner’s pre-test score did not yield a clear accuracy improvement. Altogether, the results suggest that, with the right aggregation model, learners’ subjective scores carry considerable information about the average learning gains of the resources they receive.

Predicting learning gains within-sample

Method	Pearson	Spearman
GRAM (learn γ_i^2)	0.15 ($p = 0.56$)	0.13 ($p = 0.63$)
GRAM (learn μ_i)	0.78 ($p < 0.001$)	0.70 ($p = 0.002$)
GRAM (learn μ_i , set γ_i^2 from pretest)	0.76 ($p < 0.001$)	0.75 ($p < 0.001$)
Unweighted average	0.38 ($p = 0.14$)	0.54 ($p = 0.03$)

Table 1: Accuracies, and associated p -values, of different models when predicting the average learning gains $\mathbb{E}_i[l_{ij}]$ of the resources from subjective ratings reported by learners. For aggregating learners’ subjective ratings, we consider both the unweighted average as well as the quality scores inferred using the GRAM.

6.2 Do subjective ratings predict the average learning gains for new students?

Suppose some *new* students enter the adaptive learning community. How accurately can we predict the average learning gains $\mathbb{E}_i[l_{ij}]$ of a resource j for these learners? How does this accuracy compare to that of a prediction model in which we estimate the effectiveness of each resource directly based on pre- and post-test data?

We conducted 3-fold cross-validation, where the same students never appear in more than one fold. From the training data in each fold, we use GRAM to infer the latent variables q_j from the subjective scores s_{ij} ; we use the variant in which only μ_i is learned. We then compute the correlation (Pearson, Spearman) between q_j and the average learning gains of resource j over all students i in the test set who received j . Due to the high variability in results over the 3 folds, we repeated the 3-fold cross-validation 30 times, and averaged the results over trials. In each trial, we ensured that the data were randomly partitioned such that every resource was assigned to at least 1 learner in at least 2 folds (i.e., one testing fold and one training fold).

In the cross-validation framework, computing p -values is not straightforward because the estimates from each fold are not statistically independent. Instead, we estimated the uncertainty of each correlation as the average (over the 30 trials) standard error (i.e., the standard deviation of the correlations over the $K = 3$ folds, divided by \sqrt{K}). We compare the accuracy of predictions obtained with the GRAM to the predictions by the *unweighted average* model (Section 4.1), and also to the predictions from a model that has direct access to the *test scores* (see Section 4.2). The latter is a strong comparison because it has access to actual pre- and post-test scores, whereas the other models do not.

Results are shown in Table 2. The GRAM – which utilizes only subjective scores, not test results, of the training data – is able to predict the average learning gains for new learners with higher accuracy (0.49 Pearson and 0.43 Spearman correlation) compared to the model that uses pre- and post-test data (0.36 Pearson and 0.41 Spearman correlation) to estimate the quality of each resource. Even the unweighted average of learners’ subjective ratings retains most of the prediction accuracy that could be achieved using explicit pre-

Predicting learning gains for new students

Method	Pearson	Spearman
GRAM (learn μ_i)	0.49 (± 0.11)	0.43 (± 0.11)
Unweighted average	0.32 (± 0.09)	0.35 (± 0.11)
Predict from test scores	0.36 (± 0.09)	0.41 (± 0.08)

Table 2: Accuracies (\pm their standard errors) over $K = 3$ cross-validation folds, of different models when predicting the average learning gains $\mathbb{E}_i[l_{ij}]$ of *new* learners (i.e., not used for training).

and post-test score data. All in all, our results suggest that (1) learners’ subjective ratings carry considerable information that could be useful in an adaptive learning community for deciding which resources are more effective than others, and (2) using a crowdsourcing consensus model such as our proposed GRAM can potentially yield higher accuracy than simply taking the unweighted average.

7. CONCLUSION

We investigated whether learners’ subjective opinions about the quality of learning resources (e.g., a tutorial video) are correlated with the learning gains (post-test minus pre-test) associated with receiving those resources. This could have implications for adaptive online learning communities in which open educational resources (OER) are served to students based on estimates of how effective they would be for learning: Rather than giving relatively time-consuming pre- and post-tests, the adaptive learning platform could instead simply ask learners how helpful they found the resources to be. We developed a novel Gaussian Rating Aggregation Model (GRAM) with which to aggregate many learners’ subjective scores into an overall quality estimate for each resource. Based on an experiment that we conducted on Mechanical Turk, we found that (1) subjective scores are highly correlated with average learning gains (Pearson correlation of 0.78). Moreover, (2) when predicting the average learning gains for learners who are *new* to the learning community, the accuracy (Pearson correlation of 0.49) using the GRAM from subjective scores was even better than estimating learning gains from test scores.

Future work will consider how to combine subjective scores with test data in order to arrive at improved estimation accuracy of resources’ effectiveness. Moreover, with the goal to personalize education, it would be interesting to explore how to harness subjective ratings to estimate *individual* learning gains rather than just *average* learning gains. Finally, it is important to establish whether the results we collected in our study on adult participants from Mechanical Turk generalizes to more authentic online learning communities (e.g., Khan Academy, ASSISTments).

ABSTRACT

“Wheel spinning” is the phenomenon in which a student fails to master a Knowledge Component (KC), despite significant practice. Ideally, an intelligent tutoring system would detect this phenomenon early, so that the system or a teacher could try alternative instructional strategies. Prior work has put forward several criteria for wheel spinning and has demonstrated that wheel spinning can be detected reasonably early. Yet the literature lacks systematic comparisons among the multiple wheel spinning criteria, features, and models that have been proposed, across multiple evaluation criteria (e.g., earliness, precision, and generalizability) and datasets. In our experiments, we constructed six wheel spinning detectors and compared their performance under two different wheel spinning criteria with three datasets. The results show that two prominent criteria for wheel spinning diverge substantially, and that a Random Forest model has the most consistent performance in early detection of wheel spinning across datasets and wheel spinning criteria. In addition, we found that a simple model overlooked by previous research (Logistic Regression trained on a single feature) is able to detect wheel spinning at an early stage with decent performance. This work brings us closer to unifying strands of prior work on wheel spinning (e.g., understanding how different criteria compare) and to early detection of wheel spinning in educational practice.

1. INTRODUCTION

Intelligent tutoring systems (ITS) aim to guide students towards mastery of knowledge components by providing step-by-step personalized guidance. However, there are cases where students persistently work on problems without making progress towards mastery. This phenomenon of unproductive student persistence has been called “wheel spinning” [1]. If ITSs were able to detect potential wheel spinning as early as possible, they might be able to adjust their instructional strategies accordingly to avoid wasting students’ time.

Chuankai Zhang, Yanzun Huang, Jingyu Wang, Dongyang Lu, Weiqi Fang, John Stamper, Stephen Fancsali, Kenneth Holstein and Vincent Aleven “Early detection of wheel spinning: Comparison across tutors, models, features, and operationalizations” In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 468 - 473

Beck & Gong [1] operationalized wheel spinning as failing to get three attempts correct in a row within the first 10 practice opportunities. We refer to this as “three correct in a row criterion.” They presented evidence in [3] that wheel spinning is not a rare phenomenon. Other operationalizations of unproductive persistence have since been proposed. For example, Predictive Stability (PS) is a when-to-stop policy for ITSs proposed in [5], which stops when the probability of a student getting the next step correct stabilizes. The policy uses student performance at each step to decide whether the ITS should stop giving more questions, either because of mastery or wheel spinning. The Predictive Stability++ (PS++) policy [5] provides further analysis about mastery *after* the PS policy would have stopped. This policy can detect wheel spinning under various student models. Although the two operationalizations are, at the surface, rather different, prior work has not investigated how they compare.

More generally, although prior work has introduced various machine learning models for the early detection of wheel spinning, fitted on a variety of datasets, we are not aware of any systematic comparison across models, datasets, and operationalizations. This makes it difficult for researchers to compare and establish global evaluations, which is important both for practical and theoretical reasons. Therefore, in this study, we conducted a comprehensive examination to address the following questions: (1) To what extent do different operationalizations of wheel spinning agree or disagree? (2) Which set of features leads to better predictions? (3) What is the simplest set of features that can be effective? (4) What are some good methods for early detection of wheel spinning? and (5) How early can these methods detect wheel spinning with decent performance?

2. DATASET

We used three datasets in our experiments. Two of the datasets were collected from two sections of Algebra content in the MATHia ITS [9] during the 2017-18 school year. Sections within MATHia, which is built on Cognitive Tutor technology from Carnegie Learning, provide instruction and practice on a series of KCs via multi-step problem solving tasks, each problem providing practice on several KCs (we will refer to this as the “CL1 dataset” and “CL2 dataset”). There are 132,551 student-KC pairs in CL1 dataset and 419,832 student-KC pairs in CL2 dataset. The third dataset is from a high school geometry tutor [6] (we will refer to this as the “Geometry dataset”) with 8175 student-KC pairs.

The datasets used in these experiments were exported from DataShop data [10].

2.1 Label Generation

We labeled each (student, KC) pair in our three datasets according to both the three correct in a row criterion and the PS++ policy [5]. With each criterion, there are three possible label values: *mastered*, *wheel spinning*, and *indeterminate*. A (student, KC) pair was labeled *indeterminate* if there were not enough steps to determine whether the student has or will master the KC. Following [1], we discarded (student, KC) pairs labeled as ‘indeterminate’ before training our models, given insufficient data to apply the criterion.

2.1.1 Three Correct in a Row

We generated labels for the three correct in a row criterion as follows: For each (student, KC) pair, if there were three or more contiguous correct attempts within the first 10 steps, then the (student, KC) pair was labeled *mastered* (even if there were less than 10 steps). The (student, KC) pairs that did not reach mastery with 10 or more steps were labeled *wheel spinning*. The (student, KC) pairs with less than 10 steps and no occurrence of three contiguous correct steps were labeled *indeterminate*. Under this criterion, the frequency of wheel spinning in CL1, CL2 and Geometry dataset is 6.6%, 0.56%, and 10.2% of (student, KC) pairs, respectively.

2.1.2 Predictive Stability++

The second set of labels are derived from the PS++ policy, which is defined as not reaching a mastery condition *after* a student model’s predictions of next step correctness have stabilized to a steady state [5]. In our analysis, we used Bayesian Knowledge Tracing (BKT) as the student model. On the Geometry dataset, we used BKT parameters obtained by fitting the model to data. In the other two datasets, we used the “shipped parameters,” that is, the parameters actually used by the ITS. For each step in a (student, KC) pair, BKT calculates $P_C(t)$, which is the probability of getting a correct response for the current step, as well as $P_{C|0}(t) = P(C_{t+1}|¬C_t)$ and $P_{C|1}(t) = P(C_{t+1}|C_t)$, the probabilities of a correct response on the next step, conditioned on a correct or incorrect response on the current step. When $P_{C|0}(t)$ and $P_{C|1}(t)$ converge, the stopping criterion defined in PS [5] is reached. We then determine the label of the (student, KC) pair as follows: According to PS++ [5], after convergence, when $P_C(t)$ is close enough to its upper bound, we consider the student has mastered this KC. Otherwise the (student, KC) pair is labeled as wheel spinning. For those (student, KC) pairs where the stopping criterion has never been met, we assign *indeterminate* as the label. Under this criterion, the frequency of wheel spinning in CL1, CL2 and Geometry dataset is 24.2%, 2.17%, and 13.2% of (student, KC) pairs, respectively.

2.2 Features

As we explored ways of creating early detectors for wheel spinning, we used a total of 28 features. Among these, 15 were introduced by [3]. These 15 features are extracted to analyze and record three aspects of students’ learning progress. The first aspect is students’ learning performance like ‘correct response count’ and ‘prior problem count with

hint request’, which indicate whether the student is doing well on a particular KC. The second aspect is the ‘seriousness’ of students, including ‘prior problem fast correct’ and ‘prior problem slow incorrect’. These features indicate whether the student appears to be making a deliberate effort on a particular KC. The third category of the features includes general features like ‘skill id’. In addition, we used 7 features introduced by [4], and 6 new features based on our previous research and our explorations on the Carnegie Learning dataset. A complete list of features and their descriptions can be found in the online appendix.¹

3. EXPERIMENTS AND DISCUSSION

We conducted the following experiments and analyses to answer the research questions listed in section 1.

3.1 Compatibility of Operationalizations

3.1.1 Comparing Operationalizations

Regarding Research Question (1) (to what extent do different operationalizations of wheel spinning agree or disagree?), a first observation is that the overall frequency of wheel spinning, reported above, differs substantially under the two operationalizations, with no clear pattern of one predicting more wheel spinning than the other. The confusion matrices (Figure 1, 2, 3) that compare the two operationalizations on each of the three datasets provide further insight into this divergence. For instance, in the CL1 dataset, among all (student, kc) pairs that are labeled as wheel spinning by either operationalization, the two operationalizations agree on only 22.2% of them. In CL2 dataset, the same wheel spinning agreement percentage is 14.1%. In the Geometry dataset, it is 41.6%. The agreement on wheel spinning is generally less than 50%.

Three Correct in a Row	Predictive Stability		
	Master	Indeterminate	Wheel Spinning
Master	31.15%	13.88%	10.01%
Indeterminate	0.23%	29.51%	8.60%
Wheel Spinning	0.32%	0.69%	5.61%

Figure 1: Comparison of two different criteria for wheel spinning in the CL1 dataset.

Three Correct in a Row	Predictive Stability		
	Master	Indeterminate	Wheel Spinning
Master	84.84%	2.35%	1.43%
Indeterminate	0.95%	9.48%	0.40%
Wheel Spinning	0.12%	0.10%	0.34%

Figure 2: Comparison of two different criteria for wheel spinning in the CL2 dataset.

To investigate the divergence between the two operationalizations in more detail, we present examples of (student, KC) pairs where the criteria disagree (see Figures 4 and

¹<https://tinyurl.com/edm19supplement>

Three Correct in a Row	Predictive Stability		
	Master	Indeterminate	Wheel Spinning
Master	55.96%	7.14%	1.24%
Indeterminate	10.26%	10.12%	5.05%
Wheel Spinning	1.31%	2.06%	6.86%

Figure 3: Comparison of two different criteria for wheel spinning in the Geometry dataset.

5). These visualizations show the student first attempted response on each step together with different wheel spinning metrics. Specifically, the student’s correct answers, incorrect answers, and hints for the given KC are visualized at the bottom of each graph. When there are 3 contiguous green dots within the first 10 steps (shown in a dashed-lined box), the KC will be considered mastered under the three correct in a row criterion. Shown above are $P_C(t)$, $P_{C|0}(t)$, $P_{C|1}(t)$, P_{master} , and upper bound of $P_C(t)$. A vertical, dashed line shows the stopping step for PS; the x-axis denotes the practice opportunity using a 0-based index. In most of the cases in which the three correct in a row criterion and PS++ agree with each other, there is a clear pattern in students’ responses towards mastery or wheel spinning. For example, many contiguous corrects will generally result in mastery under both criteria; many contiguous incorrect attempts will result in agreement for wheel spinning. Figure 4 shows one case where PS++ detects wheel spinning but the three correct in a row criterion detects mastery. For this specific (student, KC) pair, mastery (under both criteria) occurs past the point where PS stopped; the initial string of incorrect responses appears to have been influential.

Figure 4: An example of (student, KC) where the three correct in a row criterion detects mastery and PS++ detects wheel spinning.

Figure 5 shows the opposite situation, where PS++ gives a mastery label but the three correct in a row criterion is detecting wheel spinning. In this instance, mastery under the various criteria happens past the 10 step cutoff.

3.1.2 Discussion

We found some overlap but also substantial disagreement between the two operationalizations of wheel spinning, the

Figure 5: An example of (student, KC) where the three correct in a row criterion detects wheel spinning and PS++ detects mastery.

three correct in a row criterion and PS++. The operationalizations tend to agree when the student’s performance is obvious and steady (e.g. the student is doing extremely well or poorly on a KC, or when, as is common, there is a gradual increase in performance). However, these criteria can disagree when students’ responses fluctuate. One of the reasons is that the two operationalizations judge mastery in different ways. The three correct in a row criterion, with the explicit 10-step (or other configurable number of steps) cutoff, focuses on mastery in the early stage. Student performance after the cutoff is not taken into account. In contrast, PS++ may consider long-term performance; its mastery judgment can be made using more data, although, as seen in one of our examples, PS++ may stop too early on KCs with lower P_{learn} and an early string of incorrect responses.

3.2 Feature Effectiveness

In this section, we aim to explore the effectiveness of features we are using. In particular, we focus on Research Questions (2): Which set of features lead to better predictions; and (3): What is the simplest set of features that can be effective?

3.2.1 Feature Importance with Random Forest

In order to find a set of features for better prediction, we trained a Random Forest model and generated the feature importance graph. Feature importance of a Random Forest is measured by the total decrease in Gini impurity averaged over all the trees in the ensemble [2]. We rely on [8]’s implementation of Random Forest and feature importance and used the default hyperparameters. Figure 6 is an example of the feature importance graph. Among the set of 28 features, four are repeatedly identified as important by the Random Forest model. In all 6 scenarios (three datasets with two wheel spinning criteria), at least three of the four selected features appear in the top five most important features. Two of these features are related to students’ performance: ‘Correct Response Count’ and ‘Correct Response Percentage’. The other two features are related to the speed and attentiveness of students: ‘Exp Mean Response Time Z-Score’ and ‘Prior Step Count Normal Correct’.

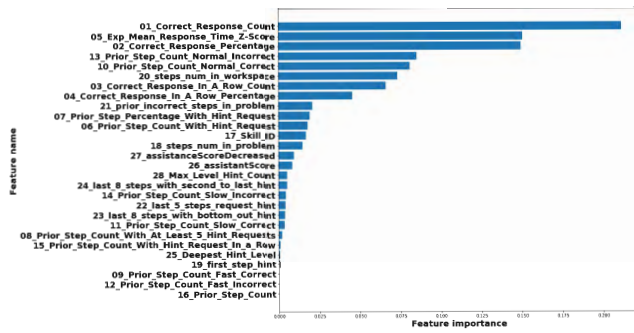

Figure 6: An example of feature importance, trained on CL1 dataset under PS++ criterion.

3.2.2 Fitting Single-feature Logistic Regression

The predictive power of very simple wheel spinning detectors is under-explored in prior literature. Here, we are interested in finding out the predictive value of individual features. Therefore, we picked 6 features that were repeatedly deemed as important in the work reported in section 3.2.1 and built 6 Logistic Regression models, each trained on one of the 6 features. We used [8]’s implementation of Logistic Regression and applied the default hyperparameters.

The results show that the detectors trained on ‘Correct Response Count’, ‘Correct Response Percentage’, ‘Correct Response in a Row Count’ and ‘Prior Step Count Normal Correct’ achieve high precision and recall when predicting the PS++ label. For example, a Logistic Regression model, trained with ‘Correct Response Percentage’ as the single feature, detected wheel spinning with 93.5% precision and 77.1% recall after just 4 steps. Generally, features involving correctness seem to be highly effective in wheel spinning detection. In addition, although the detector trained on ‘Assistance Score’ (i.e. the sum of the number of errors and the number of hints on a step) somewhat surprisingly didn’t perform as well as the rest, it still reached 68.4% precision and 60% recall in the fourth step.

3.2.3 Discussion

In our experiment, we found that the features that involve correctness of steps tend to be effective in predicting wheel spinning, independent of the criteria or datasets used. These results make sense because intuitively, if a student can get a large percentage of steps correct, then this student is likely on their way to mastering the given KC. They also lead to the question of whether we can build an effective detector that relies on correctness only. The results above show that a Logistic Regression model trained with ‘Correct Response Percentage’ is able to give us comparable result to other models, although it suffers more from the cold start problem and fluctuates more than other detectors. In addition, other aspects of the step-solving process, including time and help requested, can also be useful, as ‘Exp Mean Response Time Z-Score’ and ‘Assistance Score’ also have high feature importance while training Random Forest model. These findings indicate that certain aspects in students’ learning performance help predict wheel spinning regardless of the problem setting and tutoring system.

3.3 Early Detection Models

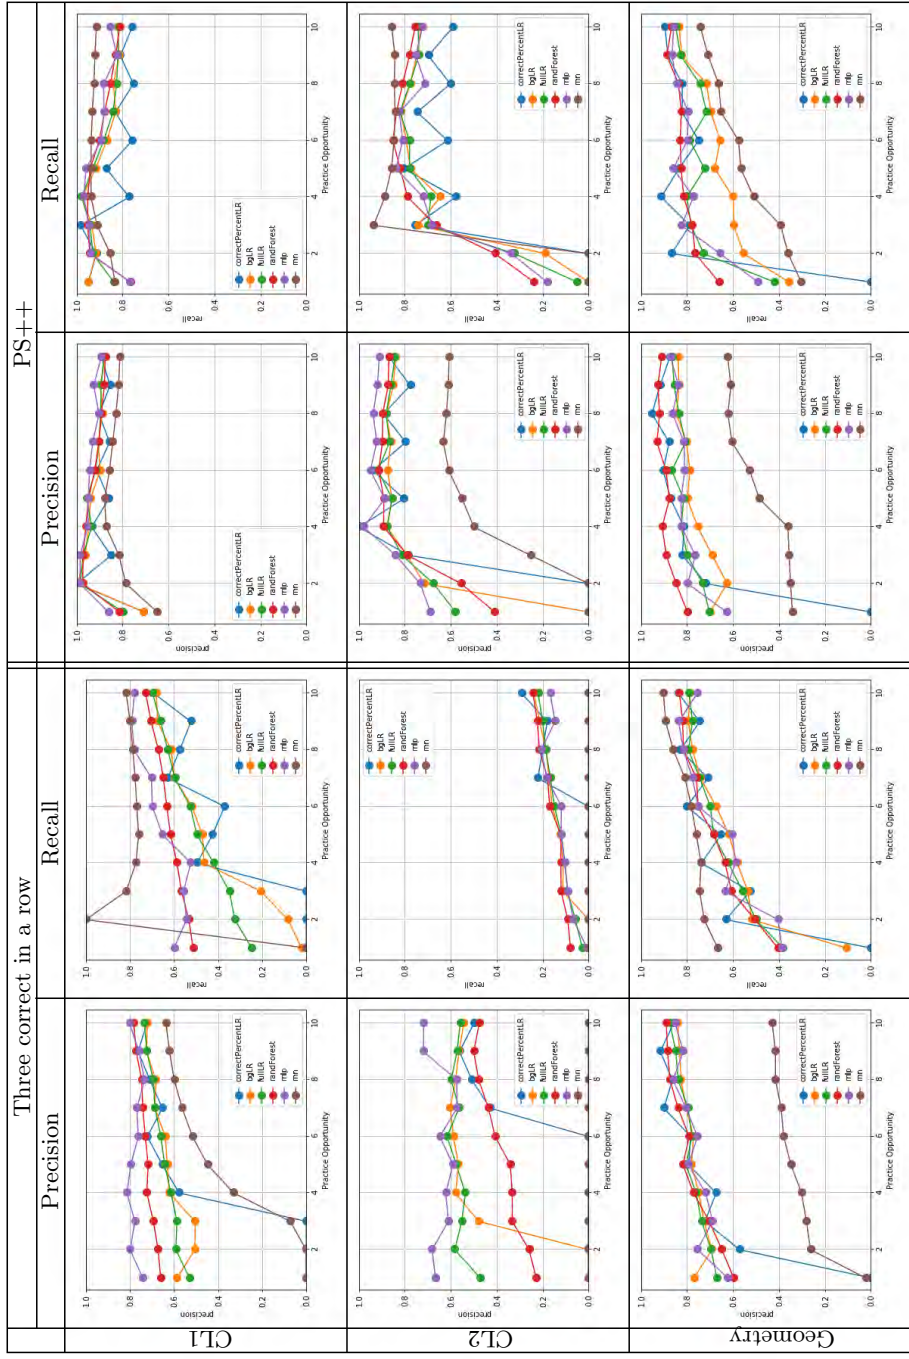

To answer Research Question (4) and (5), we trained multiple machine learning models to study their performance on early detection. We used a Logistic Regression model, trained on the same set of features as in [1], as a baseline. Another detector based on Logistic Regression was trained with the full set of 28 features. In addition, we include one of the detectors used in section 3.2.2, namely, a Logistic Regression model trained on ‘Correct Response Percentage’, to compare the performance of a simple model with that of other more complex ones. Inspired by [4], we also included a Random Forest model. Finally, we trained two neural-network-based detectors: a 5-layer fully-connected artificial neural network and a 3-layer LSTM. We split our dataset into training and testing data with a 6:4 ratio.

In order to study how early the detectors could accurately detect wheel spinning - by early we mean early in the opportunity count for any given (student, KC) pair - we fitted Random Forest, Logistic Regression and MLP models separately for each practice opportunity - that is, separately with data up to and including opportunity N , for N from 1 to the available data for the given (student, KC) pair. (The labels were computed based on all data, as described above.) Doing so was necessary for these three models as they do not have a recurrent structure to handle variable length steps and most of our features are accumulative. By contrast LSTMs are inherently recurrent, so we trained it on data from every step. We rely on [8]’s implementation of Logistic Regression, Random Forest and Multi-Layer Perceptron (MLP) and [7]’s implementation of LSTM. For Logistic Regression and Random Forest, we used the default hyperparameter provided by [8]. For MLP, we had 3 hidden layers with 64, 32, 16 units, respectively. For LSTM, we used 2 layers with 64 hidden units. For each dataset, we evaluated our detectors on the corresponding test data, and computed precision and recall for the wheel spinning class. Figure 7 shows the detectors’ performance on early detection, with two (precision, recall) plot pairs for each detector on the ‘wheel spinning’ class, one pair for each of the two operationalizations.

3.3.1 Model Performance

We found that these detectors in general perform well under the PS++ criterion. Most of them reached more than 60% precision and recall after the fourth step, and more than 80% precision and accuracy after the sixth step. Under the three correct in a row criterion, the detectors in general perform worse in terms of both precision and recall compared to the PS++ criterion. In particular, in CL2 dataset, we observed extremely low recall for all models. As foreshadowed in section 3.2.2, the single-feature Logistic Regression model (blue line in Figure 7) achieved decent performance compared to more complex models, except on the CL2 dataset. Although it tends to have lower precision and recall in earlier steps, after step 4, its performance is comparable to those of Logistic Regression trained on 15 features and Logistic Regression trained on the full feature set.

The two most accurate models are Random Forest (red line in Figure 7) and MLP (purple line in Figure 7). In particular, at the fourth step, Random Forest exhibits (77.2%, 63.5%) precision and recall on three correct in a row and

the baseline model achieves (74.9%, 58.2%) and (75.3%, 59.9%). To support comparison, we kept the hyperparameters consistent across all situations. However, if one is interested in getting even better performance, we recommend further tuning these parameters based on specific situation.

3.3.2 Discussion

The models differ in how well they generalize across datasets and wheel spinning criteria. Among them, Random Forest and MLP were those with the most competitive results. Besides its performance, Random Forest also provides an evaluation of feature importance (as in section 3.2.1) and possibly greater interpretability. In addition, to our surprise, we found that the detector trained on a single feature related to correctness consistently produced results not far behind from other detectors. Features unrelated to correctness, on the other hand, are more dependent on the context, such as differences across ITSs and usage, or difficulty of the underlying domain. However, the downside of using a single correctness-related feature is that correctness only measures one (albeit important) aspect of the students’ behavior while solving steps. Detectors like this may overlook the fact that some students can learn from solving steps and reach mastery slightly later (e.g. getting the first four steps

wrong but answering correctly on the next four) in the process. Nonetheless, this shortcoming should not undermine the power of this model. We recommend its use as a baseline model in future research.

We also find that the detectors perform worse in general under three correct in a row criterion. Even in CL2, where over 97% (student, KC) pairs are under mastery class after discarding the indeterminate class, their performance are extremely low under three correct in a row criterion while decent under PS++ criterion. We failed to come up with a definite explanation to such a phenomenon, but we hypothesize that three correct in a row criterion may not need complicated features to predict, so adding new features merely introduces noise for detectors. Another common issue we found is that these models suffer from the “cold start” problem in every dataset, model, and operationalization. Almost all models had lower than 20% precision and recall in the first three steps in all datasets and metrics on the three correct in a row criterion. This is understandable, since at the first two or three steps, the features collected are often insufficient to determine whether a student has reached mastery or is wheel spinning.

4. CONCLUSION AND FUTURE WORK

In the current work, we aim to move toward clarity and unity in investigations of early detection of wheel spinning. Prior

investigations have not compared across different models for early detection across datasets and operationalizations. To begin addressing this gap, we compared two prominent operationalizations of wheel spinning ([1] and [5]) and compared, across three datasets, the performance of several detectors that were trained with different sets of features. First, the frequency of wheel spinning across the three datasets, 0.56%-10.2% under 3-in-a-row and 2.17%-24.2% under PS++ was in line with what previously studies have reported. For example, in the two datasets used by [3], the wheel spinning ratio was 16% and 6%. Further, we found that two well-known operationalizations of wheel spinning diverge substantially in our three datasets, which is not desirable from either a practical or a theoretical perspective, as we do not know which one to apply or build on. Some typical cases on which they do not agree include getting more KC opportunities correct after [1]’s threshold and answering several consecutive steps incorrectly early followed by much improved performance on later steps. We also found that our models predict PS++ more accurately than they predict [1]’s criterion, most dramatically in the CL2 dataset, but also in the other two data sets (see section 3.3). This finding is surprising especially if one considers that our feature sets included features engineered for prior detectors of three correct in a row reported in the literature [1, 3, 4]. Therefore, it appears unlikely that the more accurate prediction of PS++ is just an artifact of the particular choice of features. What may play a role is that the three correct in a row criterion, in contrast to PS++, does not allow for the fact that KCs vary in difficulty (i.e., require different numbers of practice opportunities, on average, to reach mastery), as is by now well-established [3]. It would be highly desirable to investigate whether our key findings, the discrepancy of the two criteria and the more accurate prediction of PS++, are replicated in a wider range of datasets.

Further, when we evaluated the predictive value of 28 features, we found there is a set of common features that are effective across different datasets and criteria, namely those having to do with step correctness and assistance gained from the system. These features are essential aspects of the learning process to capture for early detection of wheel spinning. Of the 6 wheel spinning detectors we built, the Random Forest model performed consistently well across datasets and operationalizations. Combined with its ability to evaluate feature importance and its potential for interpretability, we recommend trying Random Forest when developing a wheel spinning detector for a tutoring system. In addition, to our surprise, a Logistic Regression model trained on a single feature ‘Correct Response Percentage’ achieved results that were not far behind those of more complex models like MLP. Addressing our research question of how early we could predict wheel spinning, our best model was able to make predictions with decent precision and recall as early as step 4, namely, on CL1 dataset. These results compare favorably with the accuracy achieved by prior early detectors for wheel spinning, discussed in the introduction. Note that we are not trying to recommend using the fourth step as a definitive criterion for earliness. We merely note that, as our results show, machine-learned models can do well from that particular step onward.

There are several limitations of our work that could be studied further in future work. For example, it would be worthwhile to continue to study agreement and disagreement of additional operationalizations of wheel spinning (e.g., [6]), given that the two we studied agreed to a lesser extent than expected. In addition, some hyperparameters in PS++ can be tuned for a given system, which may further support comparisons.

ABSTRACT

Peer assessment has proven to be a useful strategy for increasing the timeliness and quantity of formative feedback, as well as for promoting metacognitive thinking among students. Previous research has determined that reviews that contain suggestions can motivate students to revise and improve their work. This paper describes a method for automatically detecting suggestions in review text. The quantity of suggestions can be treated as a metric for the helpfulness of review text. Even before a review is submitted, the system can tell a reviewer when a review is lacking in suggestions and consequently advise that they be added. This paper presents several neural-network approaches for detecting suggestions and compares them against traditional natural language processing (NLP) methods such as rule-based techniques, as well as past machine-learning approaches.

Our network-based classifiers outperformed rule-based classifiers in every experiment. Our neural-network classifiers attained F1-scores in the low 90% range, outperforming the support vector machine (SVM) classifier whose F1-score was 88%. The naïve Bayes (NB) classifier had an F1-score of 84% and the rule-based classifier had an F1-score of 80%. As in other domains such as determining sentiment, we found that neural-network models perform better than the likes of naïve Bayes and support vector machines when classifying suggestions in text.

Keywords

Peer assessment, suggestion mining, classification techniques, text analytics, text mining.

1. INTRODUCTION

Peer assessment is known to have several advantages for student learning [1]. It provides students with prompt and rich feedback that helps them improve their performance and learning readiness [2]. It gives students an opportunity to learn from others by observing their approaches to solving a problem. Not only do students learn from the feedback they receive; they also benefit from reviewing others. In fact, they probably learn more from reviewing than they do from receiving feedback [3, 4, 5, 6, 7, 8]. Finally, reviews from other students may help instructors to assign more informed grades.

Gabriel Zingle, Balaji Radhakrishnan, Yunkai Xiao, Edward Gehringer, Zhongcan Xiao, Ferry Pramudianto, Gauraang Khurana and Ayush Arnav "Detecting suggestions in peer assessments" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 474 - 479

However, these advantages can only be achieved with high-quality feedback. Nelson and Schunn [2] showed that high-quality feedback comprises several features, including suggestions on how to address problems in the work. Having concrete suggestions makes the feedback actionable for the reviewee and also trains the reviewer to solve problems [2], instead of just focusing on the existence of the problems.

So it is desirable for peer reviews to contain suggestions, but it is not easy for the instructor to give students credit for making them. The instructor would have to look through each review and keep a tally. If this could be done automatically, particularly before the reviewer submits a review [9, 10], it could help reviewers to improve the quality of their feedback, which in turn would help reviewees to improve their work.

2. LITERATURE REVIEW

Before digging in further, we must first decide what constitutes a suggestion. Negi and Buitelaar [11] state that, due to the variation in the definition of suggestion, previous results may be incompatible with each other. In this paper, we define suggestions as comments that constitute advice for making improvements [12].

Suggestions normally contain some or all of the components of specificity [2]: locating the problem, identifying the problem, offering a solution to the problem. Specificity has proven to have a direct correlation to understanding. Understanding is found to be the only significant mediator that directly contributes to the likelihood of implementing the feedback, thus improving the student's work.

Some effort has been made to detect suggestions through conventional natural language processing. These NLP approaches usually utilize rules that match the feedback to a set of predefined linguistic patterns, as well as part-of-speech (POS) tagging and a carefully crafted thesaurus relevant to each domain on which the approach is going to be implemented [13, 14, 15]. The main drawback of these approaches is that they require the knowledge of engineers to define the rules and patterns in the software logic. However, it is almost impossible to foresee all possible rules and patterns that indicate the existence of suggestions in a text document. Thus, as the number of patterns and rules grow, it becomes very difficult for engineers to maintain the software.

Another approach that has shown promising results for detecting patterns is based on machine-learning techniques. For instance, researchers have utilized machine-learning methods such as SVM with some degree of success to find patterns that indicate the sentiment polarity of a text [9].

Machine-learning algorithms are able to discover patterns and rules automatically based on training samples [16]. For software

engineers, this is a game-changer since it allows them to keep the complexity of the software consistent and manageable. There are many machine-learning algorithms that can be used for classifying text as to whether it contains suggestions or not, such as decision trees (DT) and support vector machines [17]. Machine-learning approaches can usually outperform rule-based approaches once they are trained with sufficient and representative samples that have been labeled. However, obtaining labeled data is usually very expensive.

Recently, the neural network approach has stood out for its ability to solve classification problems in different domains, e.g., image and voice recognition, and text classification [11]. This work tries to apply neural networks to suggestion detection and compares the results with the rule-based and traditional machine-learning classifiers.

3. DATA

In this experiment, we used a balanced dataset of peer reviews with a total of 3878 peer reviews, each labeled as containing a suggestion (1) or as not containing a suggestion (0). It is extracted from the Expertiza [18, 19] platform, which we would describe later on in this section. The dataset has two main components: (i) the input text, and (ii) a label indicating whether suggestions were present in the text. The datasets for the neural network classifiers were broken down into an 80–10–10% split for training, validation, and test sets. For the naïve Bayes classifier and the support vector machine classifier, split for training and test sets was 90-10%. All the models were trained and tested on the same dataset.

The platform we mentioned in the previous paragraph, Expertiza, is a web-based peer-review system that allows students to exchange ideas and build shared knowledge. It facilitates anonymous reviews for students' submissions. In this paper, we use reviews submitted to Expertiza to test our approaches. Authors who received reviews manually labeled 15,067 review comments as to whether they contained a suggestion. The labeling of these reviews was incentivized by giving extra credit to students in a class who tagged review comments. A team made up of the instructor, TAs, and authors of this paper went through the labels and removed labels assigned by students whose labels were clearly not trustworthy. Untrustworthy labels included random labels unrelated to review content, all no's or all yes's on reviews with obvious variety of status of containing suggestions. Inter-rater reliability of the dataset was calculated between each team of students labeling peer reviews with a Krippendorff alpha [20] of 0.69 before removing unreliable labels and 0.74 afterwards. Students receiving these reviews were an ideal choice for annotating these reviews, since the reviews were of their own work. Thus, they were capable of judging whether they really contained suggestions. In the preprocessing stage, entries that are invalid to the experiment, such as blank entries, duplicated entries, entries with unrecognizable symbols and marks, as well as html tags, were striped from the dataset. After preprocessing, the dataset contained 5,842 entries without suggestions, and 1,939 entries with suggestions.

With an imbalanced dataset, the process of machine learning is greatly compromised. Classifiers such as naïve Bayes that have been trained on too great a prevalence of a single label type can create a classifier that will only predict that single label. Machine-learning algorithms tend to focus much more on a prevalent class and much less on rare cases, even if the rare cases are trustworthy [21].

Table 1: Sample review comments.

Review Comment	Contains a suggestion?
"Very well written and very obvious how much of an impact the refactoring had."	No
"Yes, all the functionality are covered in the design document."	No
"The test plan talks about automated tests, but then goes on and talks about 2 manual testing scenarios. Details for automation test cases are missing. If the team does not plan on writing automated test cases, then it should be mentioned in the documentation. Otherwise, the team should provide more details about the test plan for automated test cases."	Yes
"Code is good. Just in tests, the code could've been reduced in some cases where same object is being mocked multiple times. "	Yes

One way to deal with this problem is to apply selection techniques. A well-known method is to down-sample the dataset. One should always keep all rare positive samples that need to be focused on and only prune out negative samples [22].

We applied this technique on our dataset in order to minimize the impact of an imbalanced dataset. Down-sampling kept all 1,939 of the positive cases in our dataset and randomly selected 1,939 negative cases to form a new balanced dataset that we used for analysis. Table 1 shows sample review comments with their respective labels. The dataset is available upon request.

4. METHODOLOGY

This section describes the methodology for each classifier. Our input data for these Classifiers is document level review text instead of sentence level, frequently we would observe students describing their solutions in sentences or even paragraphs, and we believe keeping them in their original form would be beneficial for the study. Currently, we are rating the quality of a review based on the presence of a single suggestion. Later on, we can generalize our approach to count the number of sentences that contain suggestions.

4.1 Traditional Machine Learning and Rule-based Methods

Section 4.1 discusses the formation of the rule-based, naïve Bayes, and support vector machine classifiers. Text preprocessing in the form of stop-word removal and stemming was not used except for stemming the data for the naïve Bayes classifier. The reason behind this was due to decreased classifier performance by experimenting with these preprocessing techniques and then testing the classifiers.

4.1.1 Rule-based NLP Methods

Part-of-speech tagging was used to determine the word class of each processed word. The relevant tags used for this classifier included MD (modal auxiliary), VB (verb, base form), VBZ (verb, present tense, 3rd person singular), VBP (verb, present tense, not 3rd person singular), NNS (noun, common, plural), and NNP (noun, proper, singular).

The idea and rules for this rule-based classifier were derived from Gottipati et al. [17]. We used pattern-matching and part-of-speech tagging methods, based on the work of Brun and Hagège [14], Bird et al. [13], and Marcus et al. [15]. The patterns we used are as follows.

- The first rule utilized a pattern-matching technique that locates specific phrases and keywords that indicate the likely presence of a suggestion. The phrases used included “have more”, “suggestion”, “perhaps”, and “better if”.
- The second rule uses part of speech tagging through the Natural Language Toolkit (NLTK) [13] to find a sequence of verb pairs in a review. If a word was tagged as a modal (MD) and the word directly following this was tagged as either of the verb types VB, VBZ, or VBP, then the review would be classified as a suggestion. For example, in the sentence “You should have included a diagram to visualize your results.” the words “should have” would be tagged as MD and VB respectively. This sentence would be classified as a suggestion.
- Following Gottipati, the third rule also used POS tagging. Reviews were classified as a suggestion if a word tagged NNS or NNP was followed by a word of type VB, VBZ, or VBP. This is similar to rule 2 and it was used due to the fact that some words would be labeled with different tags depending on whether they were the first word in a sentence or were located within the sentence. An example of this rule would be the processing of a sentence such as “Could include more examples in your lab report.” where the words “Could include” are tagged as NNP and VBP respectively by the NLTK POS tagger. It is important to note that a word such as “Could” will be tagged as NNP or MD depending on whether it starts a sentence or not. This would classify the sentence as a suggestion. Rule three was later removed from the classifier due to decreased performance as discussed in the results section.

4.1.2 Naïve Bayes

The Naïve Bayes classifier was formed using a train-and-test split of 90-10%. The functionality for creating this classifier is provided by libraries from Scikit-learn [23]. A pipeline of transformers was used to facilitate the construction of the classifier. These transformers include a count vectorizer that converted a collection of text documents to a matrix of token counts for future use. Then the count matrix was transformed into a normalized tf-idf representation to form the linguistic features. These fractional counts from the tf-idf representation then enabled the naïve Bayes classifier to fit the model. As previously noted, stemming the data did result in a slight increase in classifier performance, therefore composing part of the preprocessing for the final model.

4.1.3 Support Vector Machine

The support vector machine classifier was formed using a similar approach to that of the naïve Bayes classifier. The train-and-test split was 90-10%. The same count vectorizer and tf-idf transformer were used to prepare the data as with the naïve Bayes model. Scikit-learn’s [23] stochastic gradient descent training for a linear model was then used to form the support vector machine classifier.

4.1.4 Tools: Traditional Machine Learning and Rule-based

The Python natural language toolkit [13] was used for tokenization and part-of-speech tagging to prepare the text for analysis by the rule-based classifier. Stop-word removal from NLTK was attempted in the rule-based and naïve Bayes classifier, though later abandoned due to the exclusion of vital words for finding patterns

for suggestions, which decreased classifier performance. The Python library Pandas [24] was used to read the dataset into a data frame for reference within the program. Scikit-learn [23] was also used to calculate and present the resulting F1-score for the classifiers. Scikit-learn provided feature extraction and linguistic-feature processing for the naïve Bayes and support vector machine classifiers. The Scikit-learn functionality utilized included a count-vectorizer and tf-idf transformer to prepare the data for classification by these two classifiers.

4.2 Artificial Neural-Network Methods

Neural networks are a state-of-the-art method when it comes to classification. They generally tend to perform well across domains as well as across different types of data such as images, text, and speech. The core idea behind this work is to convert the task of detecting suggestions into a text-classification task and using neural networks to perform this classification. Neural networks work well for this kind of text classification. This is especially true for any kind of recurrent model, such as RNN or LSTM. Recurrent models are widely used for processing any kind of sequential data such as text, speech, and patterns. This is due to their inherent ability to process data in a sequential manner, one step of the sequence at a time. Thus, they are an ideal choice for tasks involving text, such as text classification and text generation.

In this paper, we have focused on utilizing recurrent models to perform text classification. More specifically, we focus on LSTMs and bi-directional LSTMs to achieve the best performance. In addition to the aforementioned recurrent models, we also explore the feasibility of using convolutional neural networks (CNNs) to perform the same tasks. CNNs have traditionally been used to deal with images, but there has been a recent trend toward using them for text-classification tasks. CNNs are not as optimized as recurrent models are for inputs in the form of a sequence, but they offer other benefits such as significantly improved model training times. CNNs can be used either on their own or in conjunction with recurrent models such as LSTMs. We implemented both variants. As is the norm with applying CNN’s to text classification tasks, we used a 1-D CNN everywhere in this paper.

4.2.1 LSTM

LSTM networks are a type of RNNs (Recurrent Neural Networks). They improve upon RNNs by avoiding their single biggest pitfall, the inability to capture long-term dependencies. They incorporate memory into the network in the form of a cell state, thus allowing for relevant information to be retained for long periods of time. LSTMs are preceded by word embeddings, and these embeddings may be pre-trained or not. In this work, we used pre-trained word embeddings only with the Bi-LSTM model which will be discussed next. We do not use pre-trained word embeddings with the “vanilla” LSTM model. For the vanilla LSTM model, we use the embeddings trained as a part of the Keras [25] embedding layer. We use an LSTM of size 100 (100 hidden units). We use dropout as a regularization mechanism to try to combat overfitting. Finally, we use a sigmoid layer to make the predictions.

Input	Embedding	Dropout	LSTM	Dropout	Dense
In: 50	In: 50	In: 50,100	In: 50,100	In: 100	In: 100
Out: 50	Out: 50,100	Out: 50,100	Out: 100	Out: 100	Out: 1

--->

Figure 1: LSTM Architecture

Figure 1 shows the LSTM architecture that we implemented with a detailed description of its various layers and their respective shapes in Keras.

4.2.2 Bidirectional LSTM

Bidirectional LSTMs are an extension of LSTMs. A drawback of Vanilla LSTMs is that they can learn representations only from the previous time steps. This means that when processing a given word, the model only has access to all the words that came before this word. This way, the model might lose out on a lot of valuable and relevant information that might be present after the word that is currently being processed. In order to combat this problem, we need to be able to look ahead of the current word. A Bidirectional LSTM has the ability to use words both preceding and following the word being processed. This should give it an edge over a vanilla LSTM. We use the pre-trained Glove embeddings [26] in tandem with the bidirectional LSTM. We chose a Glove embedding that generates a 300-dimensional vector embedding for every word. The size of this bidirectional LSTM is 150 (150 hidden units). As with the vanilla LSTM, we use dropout for regularization and sigmoid as the final classification layer.

Input	Embedding	Dropout	BiLSTM	Dropout	Dense
In: 50	In: 50	In: 50,300	In: 50,300	In: 300	In: 300
Out: 50	Out: 50,300	Out: 50,300	Out: 300	Out: 300	Out: 1

-->

Figure 2: Bi-LSTM Architecture

Figure 2 shows the Bidirectional LSTM architecture that was implemented with a detailed description of its various layers and their respective shapes in Keras [25].

4.2.3 CNN

CNNs are a type of feed-forward deep neural network that is primarily applied to data in the form of images. They require minimal pre-processing and are shift invariant. They are used in the domains of image and video recognition, recommender systems and, more recently, NLP. They have already achieved human-level performance on image recognition and have recently made the transition to text classification, where they have been shown to work surprisingly well. CNNs work well with images because they preserve the 2D spatial orientation of the input image. In contrast, texts have a 1D orientation, wherein the sequence of the input words matter. So, we use a 1D CNN to be able to capture this orientation in text. Here we utilize a 1D CNN, followed by a dense layer of size 100. We continue to use sigmoid for the final classification.

Input	Embedding	Dropout	Conv1D	GlobalMax Pooling	Dense	Dropout	Dense
In: 50	In: 50	In: 50,100	In: 50,100	In: 48,100	In: 100	In: 100	In: 100

-->

Figure 4: CNN+LSTM Architecture

Figure 3 shows the CNN architecture that is implemented in this paper with a detailed description of its various layers and their respective shapes in Keras [25].

4.2.4 CNN + LSTM

It is interesting to combine the CNN and the LSTM models. LSTM models are very well suited for text classification, but due to their inherent design and sequential processing, they take a long time to train. CNNs, on the other hand, are highly parallel in nature and process the entire data at once. This allows for very short training times, especially when compared to an LSTM. To avoid this shortcoming of LSTMs, we add a convolutional layer before the LSTM layer. This convolutional layer passes a filter over the input text and generates a high-level representation of the input. This high-level representation is then fed to the LSTM instead of the word embeddings. This has a significant positive effect on training times of the LSTM model. Thus we can achieve the best of both worlds by following a CNN with an LSTM, and reducing the training times of the LSTM while retaining its sequence-processing abilities. In this paper, we use a 1D CNN followed by an LSTM of size 100 (100 hidden units). As is the case with all other models, we stick with dropout for regularization and sigmoid for the final classification layer.

Figure 4 shows the CNN+LSTM architecture that is implemented in this paper with a detailed description of its various layers and their respective shapes in Keras [25].

4.2.5 Tools: Artificial Neural Network

Keras was the deep learning framework of choice that was used to implement the various neural network models. Scikit-learn's classification report was used to generate metrics including precision, recall, and F1-Score. The inbuilt tokenizer from Keras was used to tokenize the peer reviews before feeding them to the neural network models.

For each of these networks, a series of hyper-parameters are isolated and tuned, which include parameters such as input batch size, number of memory states, recurrent dropout rate, dropout rate between layers, padding rules, CNN window size and stride size, activation methods, number of epochs to train. Based on classification accuracy on the validation dataset, we have tuned the network into their respective final stages and have achieved results described in the next section.

5. RESULTS

Table 2 displays the total number of suggestions present in the peer review dataset used for this experiment, along with a summary of the weighted average F1-scores. Dataset reformatting was accomplished prior to this so that the number of suggestions to non-suggestions resulted in a mostly equal proportion within the dataset. Abbreviations for the tables are as follows: Rule (as itself), NB (Naïve Bayes), SVM (Support Vector Machine), and N1-N4 as the neural network classifiers (LSTM, BiLSTM, CNN, and CNN+LSTM respectively).

From the results obtained by testing on the Peer Review dataset, we found that the LSTM, CNN, and CNN+LSTM neural network architectures outperform the other classifiers used in this experiment. This relates to our discussion in the literature section where the neural network approaches have demonstrated the greatest potential

Table 2: Accuracy of classifiers on peer-review dataset

# of comments		3878
# containing suggestions.		1939
F1 score	Rule	0.80
	NB	0.84
	SVM	0.88
	N1	0.91
	N2	0.93
	N3	0.92
	N4	0.90

for text classification tasks like suggestion detection. The BiLSTM classifier was the second best at detecting suggestions, followed by the support vector machine, rule-based, and naïve Bayes classifiers. Tables 3 and 4 display the extended breakdown of the results of the classifiers.

These results show precision, recall, and F1-score as generated by the classification report function by Scikit-learn. The number of data points that are false and true is noted in the Support column. The rates of classification for both positives and negatives are included in the table as False and True, along with the support for each. Finally, the weighted average was used to demonstrate the classifier's overall effectiveness by combining the metrics for positives and negatives using a weighting based upon the quantity in Support.

The weighted average is calculated by taking the mean of the false and true predictions by their relevance in the dataset. In terms of these results tables, the weighted average is determined by multiplying the metric (precision, recall, or F1-score) of the false predictions by the percentage of these predictions over the whole dataset. The same calculation is made for the true predictions. Then the value calculated by the False row is added to the value calculated for the True row.

The classifiers performed similarly on overall accuracy, with some deviation in the performance for False and True observations. The F1-scores of the classifiers ranged from 80% up to 93%, where the neural network classifiers were close in performance. Rule 3 of the rule-based classifier was removed due to the tagging of some

words as NNS or NNP that were not indicative of a suggestion. This resulted in numerous false positive classifications and therefore a net loss of overall performance. Rule 2 can also have result in a high false-positive classification rate since it does not consider the context of a tagged pair of words within a sentence, although it was the most effective rule at finding suggestions.

6. DISCUSSION AND FUTURE WORK

In this study, we have compared the performance of a few neural network classifiers against a rule-based classifier on suggestion detection towards multiple datasets. We found that neural network classifiers outperformed existing rule-based and traditional machine learning classifiers across the board.

Despite using a small dataset, we were able to obtain F1 scores in the low 90% range. This demonstrates the potential of the neural network classifiers. When large-scale datasets are obtained, classification scores in the upper 90% range will be probable, therefore reaching the high accuracy levels that some sentiment analysis models have obtained.

One of the biggest challenges we've encountered in this study is the insufficient amount of readily labeled data in hand. Most of the times we would need to manually label datasets that we acquired. Larger datasets would help with tuning and training the classifier. They would also give us the opportunity to train on more balanced sets of data, while not excluding too large of a portion of the overall dataset. Larger training samples would help alleviate the concern that the models may not be able to generalize to new input strings that aren't similar enough to the current training set. However, as noted in Section 2 we removed around 7000 duplicate observations from the dataset, indicating that there are commonly occurring review comments that the model would be tuned for. Additional pattern-matching phrases can be added to the rule-based classifier to improve its accuracy, although additional conditions would be required to consider the context of the phrases within a larger body of text. Also, the inclusion of more types of classifiers such as a decision tree can provide an extended comparison of what classifiers perform best for this text classification task.

As discussed in the introduction, the domain of primary interest revolved around peer reviews. Later on, we might find a way to let instructors use the classifier to grade the quality of peer reviews. We would seek feedback on the effectiveness of the classifier, and suggestions for its improvement. This system could also notify the reviewer that a review should have more

Table 3: Breakdown of accuracy of non-neural network classifiers on peer review

Table 4: Breakdown of accuracy of neural-network classifiers on peer review

Peer review	Precision				Recall				F1 score				Support
	N1	N2	N3	N4	N1	N2	N3	N4	N1	N2	N3	N4	All
False	0.90	0.94	0.90	0.90	0.92	0.93	0.94	0.90	0.91	0.93	0.92	0.90	189
True	0.92	0.93	0.94	0.90	0.90	0.94	0.90	0.90	0.91	0.93	0.92	0.90	199
Avg.	0.91	0.93	0.92	0.90	0.91	0.93	0.92	0.90	0.91	0.93	0.92	0.90	388

suggestions. Furthermore, the reviewer could have the opportunity to identify any suggestions that were missed by the system. This would function as a useful method for generating labeled training data. These missed suggestions indicated by the reviewer could enable analysis in the form of determining what types of sentences are not being properly detected as suggestions. This system could be deployed as a supplement to instructor grading until enough data has been obtained to train a sufficiently accurate classifier for automatic suggestion extraction.

7. CONCLUSION

In this paper, we have demonstrated several models that parse and classify suggestions. The greater performance of neural network architectures over rule-based methods in this task demonstrates the advantage of classifiers that train on text in a certain domain, rather than following strict rules for classification. Furthermore, forming an extensive list of phrases and keywords that improve a rule-based classifier's performance in a domain is more time consuming than training a statistical classifier. While rule-based approaches have the advantage of being simpler to implement and not requiring data to train on, they are typically outperformed by statistical classifiers provided they have access to enough labeled data.

ABSTRACT

We propose a general-purpose method for detecting cheating in Massive Open Online Courses (MOOCs) using an Anomaly Detection technique. Using features that are based on measures of aberrant behavior, we show that a classifier that is trained on data of one type of cheating (Copying Using Multiple Accounts) can detect users who perform another type of cheating (unauthorized collaboration). The study exploits the fact that we have dedicated algorithms for detecting these two methods of cheating, which are used as reference models. The contribution of this paper is twofold. First, we demonstrate that a detection method that is based on anomaly detection, which is trained on a known set of cheaters, can generalize to detect cheaters who use other methods. Second, we propose a new time-based person-fit aberrant behavior statistic.

Keywords

MOOCs; Learning Analytics; Anomaly Detection; Cheating

1. INTRODUCTION

Academic dishonesty is one of the endemic problems of higher education. Some studies have reported that up to 95% of college students are engaged in some kind of dishonest behavior [10, 4, 9]. The anonymity of online environments makes it easier for students to cheat [8]. In addition, online learning environments tend to be more heterogeneous, and students might differ significantly in their perception of what constitutes cheating [3]. These might lead students to look for ways to exploit the properties of a learning environment to gain credit without learning the contents [2, 3].

Within the context of online learning, Massive Open Online Courses (MOOCs) have greatly garnered the attention of the media and researchers over the last decade [5]. Estimates are that during 2018 there were more than 100M MOOC learners, more than 11k MOOCs, and more than 900 institutes involved [18]. These large numbers tell some of the story of how MOOCs change the educational landscape.

Giora Alexandron, José A. Ruipérez-Valiente and David Pritchard "Towards a General Purpose Anomaly Detection Method to Identify Cheaters in Massive Open Online Courses" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 480 - 483

MOOCs offer certificates that do not have formal academic status, but are still perceived as valuable, for example in the labor market. Thus, it is not surprising that several studies reported on cheating in MOOCs, for example by plagiarizing peer-review assignments [7]. One of the main cheating methods that was discovered in MOOCs is Copying Using Multiple Accounts (CUMA). Several studies have been successful at detecting CUMA by implementing probabilistic algorithms [13], heuristics [2], and machine learning [17]. A different cheating method, unauthorized collaboration, was reported in [16], and detected using a method that is based on proximity of submissions in time. We note that CUMA and unauthorized collaboration are strictly forbidden by all the major MOOC platforms, e.g., edX¹.

With major MOOC providers currently pivoting towards the direction of professional development and online degrees [15], there is an even greater need for robust techniques to prevent and detect cheating, which can generalize and scale across platforms, topics and courses. The goal of this study is to develop general detection techniques that can identify cheating without assuming a specific pattern. The rationale is to rely on behavioral patterns that capture various types of aberrant behavior, rather than relying on temporal patterns that are specific to a certain method of cheating.

In previous work [1] we *hypothesized* that anomaly detection can be used to build such a general purpose classifier, which 'bootstrap' from one type of cheating to detect other types of cheating. However we were unable to demonstrate this, due to lack of a reference model. The current study extends [1], and demonstrates that a general-purpose cheater detector that is based on anomaly detection can be trained on one type of cheating and then be used to discover other type of cheating. The detector is based on measures of aberrant behavior, such as Guttman Error [11]. As an additional contribution, we also formalize a new time-based aberrant behavior person-fit statistic that was proved useful in discriminating cheaters.

2. METHODOLOGY

2.1 Procedure

The overall rationale of this research is to develop a 'bootstrap' process in which a detector that is trained on one type of cheating is used to build a more general classifier that can detect other types of cheating as well. In our case, the first

¹<https://www.edx.org/edx-terms-service>

type is CUMA, and the other type of cheating is unauthorized collaboration, for which we also have a detector that serves as a reference model.

To test this approach, we use the following cross-validation procedure (with $K=3$, repeated 500 times). First, we train a classifier on a test set, under the assumption that we know to detect only CUMA. In practice, this means that in the test set only CUMA users appear as positive examples (though it may include collaborators data, depending on the random assignment to training/held-out datasets). Second, we use this classifier to classify the held-out dataset. On this set, we check the recall with respect to collaborators. That is, we compute how many of the collaborators in the test set were classified as ‘cheaters’ by the algorithm, and compare it to the fraction of non-cheaters that were identified as cheaters.

In addition, we evaluate the performance of a classifier that is built on a dataset in which both types of cheaters are tagged as positive examples. The rationale for this evaluation is to support future research, in which we intend to check the generalizability of this classifier not only from one method of cheating to the other, but also between MOOCs.

2.2 Data

We use data from an Introductory Physics MOOC offered by the third author through edX on summer 2014. The course consists of 12 required and 2 optional weekly units. A typical unit contains three sections: Instructional e-text/video pages (with interspersed concept questions, aka checkpoints), Homework, and Quiz. Altogether the course contains 273 e-text pages, 69 videos, and ~ 1000 problems. About 13500 students registered to the course, and from them, 502 earned a certificate. This research use the data of 495 certificate earners (7 were omitted due to technical reasons).

2.3 Detecting Cheaters

We define as cheaters those users who use methods that break the code of honor (such as creating multiple accounts or sharing responses with peers) to achieve credit in a way that does not rely on learning. We have algorithms that can detect two specific types of cheating – CUMA, and unauthorized collaboration.

2.3.1 Copying Using Multiple Accounts (CUMA):

To detect CUMA users, we use the algorithm of [2]. It detects 65 users ($\sim 13\%$ of the certificate earners).

2.3.2 Collaborators:

To detect collaborators, we use the algorithm of [16]. Overall, it detects 20 of the certificate earners. However, among those learners, 11 were also classified as CUMA users by the previous algorithm. In these cases, we decided to give priority to the CUMA algorithm, as it represents a more specific behavioral pattern. Hereafter, we refer as ‘collaborators’ to the 9 accounts who were not CUMA users.

2.4 Feature Engineering

We use the following features, divided into three groups:

Video use:

The rationale for this set of features is that cheaters tend

to spend less time on learning resources [1]. As videos are the main learning resource in most MOOCs, this feature can generalize between courses.

i. Watching time: (Log of) The total amount of time, in seconds, that the user spent watching videos.

ii. Fraction of videos watched: The fraction of videos watched. A video is considered as ‘watched’ if the user played more than 30 seconds of it.

Students Performance:

iii. Correct on first attempt: The fraction of the items that were solved correctly on first attempt.

iv. Mean time to correct: The average time on task, for items solved correctly.

v. Fraction of correct-in-less-than-30 seconds: The fraction of the items that were solved correctly in less than 30 seconds. The 30-second threshold is taken from [14].

Person-fit statistics:

vi. Guttman Error (GE): The number of item pairs in which an easier item is answered incorrectly and a more difficult item is answered correctly, normalized by the total number of pairs [11]. To make our method more general, we use the non-parametric variant, as parametric models (e.g. 2PL IRT) are difficult to fit on MOOCs data. It is computed in *R* using the package *PerFit* [19]

vii. Guttman Error on time-on-task (GE-time): This is a new aberrant behavior person-fit statistic that we propose. It basically applies the notion of Guttman Error to time-on-task. It is described in more detail in the Appendix.

2.4.1 Z-scores and Feature Selection

The independent variables were standardized using *z*-scores, to enable comparing the relative importance of features based on standardized logistic regression coefficients [12], and to allow (in the future) generalizing to other MOOCs. For feature selection, we use a LASSO logistic regression and pick the features that have a non-zero coefficient (the tuning parameter λ is chosen via cross-validation). This is done in *R* using the package *glmnet* [6].

3. RESULTS

This section is organized as follows. First, we report on the results of the feature selection. Second, we present the distribution of the features among CUMA, collaborators, and non-cheaters. Third, we present the performance of the classifier trained on the CUMA users, when used to detect collaborators. Fourth, we report on the performance of a classifier that is trained on both type of cheating.

3.1 Feature Selection

The features with non-zero value are GE, GE-time, fraction of videos watched, and fraction of questions answered in less than 30 seconds.

3.2 Group Differences

Figure 1 presents the differences between the three groups – CUMA users (red), collaborators (black), and non-cheaters (blue), with respect to the four features.

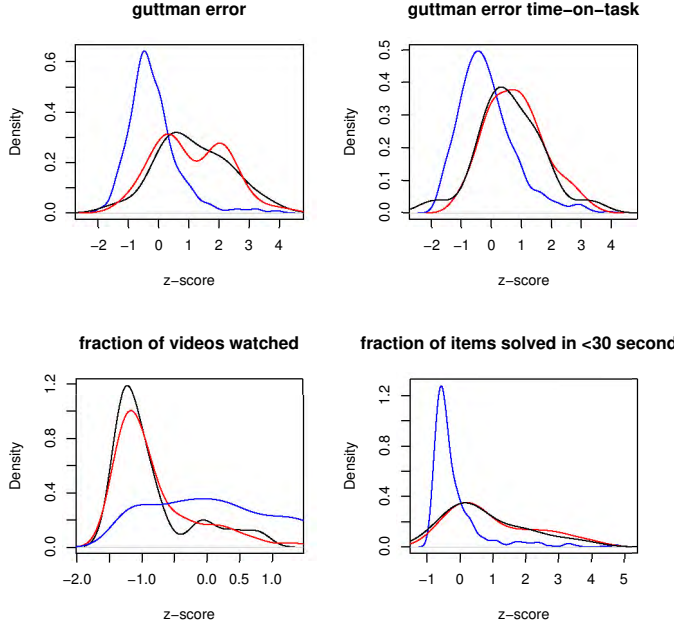

Figure 1: Distribution of the independent variables among CUMA users (red), collaborators (black), and non-cheaters (blue).

3.3 Detecting unauthorized collaboration with a classifier build on CUMA

As described in Section 2, we train a logistic regression model that receives a training set with only ‘CUMA’ users tagged as positive examples, and use it to detect ‘collaborators’. To ensure that we accurately simulate a scenario in which no information on collaborators exists during the training phase, the training set is used for fitting the model and tuning hyper-parameters, and for model-selection. Collaborators might exist in the training data (depending on the random assignment to training/test), but as negative examples (i.e., non-cheaters).

The results ($recall = \frac{TP}{TP+FN}$) of applying this cross-validation process with $K = 3$, repeated over 500 times, are presented in Figure 2. Overall, $mean(recall) = 0.72$, $sd = 0.12$.

For negative examples (neither CUMA nor collaborators), the mean amount of miss-classification ($\frac{FP}{FP+TN}$) is 0.16 ($sd = 0.01$). This means that a collaborator is 4.5 times more likely to be classified as ‘positive’, than a non-cheater.

3.4 Building a general classifier

Next, we turn to build a classifier on a dataset that contains both types of cheaters as positive examples. The rationale that underlies this is to build a classifier that can 1) ‘bootstrap’: use data that includes two types of cheating to discover additional ones; and 2) build a global classifier that can (hopefully) generalize across MOOCs.

1. **Feature Selection.** This yields the same set of features as reported above.

2. **Performance of the classifier.** We evaluate the per-

Figure 2: Fraction of collaborators identified by the classifier.

Table 1: Confusion matrix.

		Predicted	
		False	True
Actual	False	377	45
	True	22	51

formance of the classifier using cross-validation and by observing the in-sample classification error. For cross-validation, we measure the AUC of 500 5-fold cross-validation runs. The results are presented in Figure 3. $mean(auC) = 0.85$, $sd = 0.01$.

The confusion matrix for in-sample classification is given in Table 1. The classifier identifies 45 additional users as ‘cheaters’. Applying the previous results, we can hypothesize that among these, ~ 35 are ‘real’ cheaters who are not detected by our previous algorithms, and that ~ 10 are true false positives.

Figure 3: AUC of the classifier

4. DISCUSSION

In previous work [1] we *hypothesized* that anomaly detection can be used to build classifiers that can generalize from

known cheating methods to *unknown* ones. However, in our previous work we were unable to provide an empirical evidence for this, due to lack of reference model on a second type of cheating.

The current paper re-visits this approach, exploiting the fact that we now have a dedicated algorithm for detecting unauthorized collaboration, which serves as a reference model. Based on this, we demonstrate that an anomaly-detection based classifier can generalize from one type of cheating to another with high accuracy.

The classifier uses 4 aberrant behavior features. One of them is a new time-based aberrant behavior person-fit statistics that we propose, which was found to be very effective in discriminating cheaters. We name it *Guttman Error-time*.

The power of our approach lies in the fact that 1) it does not rely on prior assumptions on the cheating method, and thus does not require dedicated algorithms that are tailored to a specific method; and 2) the features that it uses are relatively simple to compute, and do not rely on fitting sophisticated parametric models (e.g., IRT). This makes our method scalable and easy to implement across contexts.

Future research. In the future we intend to study whether this method can generalize not only between different methods within the same course, but also between courses.

APPENDIX: Guttman Error-time – a new time-based person-fit statistic

Guttman Error-time applies the idea of *Guttman Error* to time-on-task. Let us define the following notations: $mean_ttc(u)$ = the mean time-to-correct of user u on all the items u solved correctly.

$ttc(u, i)$ = time-to-correct of user u on item i .

Now assume we have the Time-To-Correct matrix TTC with $TTC[u, i] = ttc(u, i)$

Let us build a new matrix Boolean-TTC, such that:

Boolean-TTC[u,i] = 0 if $ttc(u, i) > mean_ttc(u)$, 1 otherwise.

This means that an item on which many students were slower than usual, will have a lot 0's in its column. Intuitively, this is the equivalence of a ‘hard’ item in the correct-on-first-attempt matrix. Now, we define:

$GE - time = GE_{normed}(Boolean - TTC)$

A Novel Use of Educational Data Mining to Inform Effective Management of Academic Programs

ABSTRACT

In outcome-based academic programs, Program Educational Objectives (PEOs) and Student Outcomes (SOs) are two cores, which are mapped to each other in a hierarchical manner. This paper presents a novel application of educational data mining to discover useful knowledge on these components. More specifically, it applies association rule mining techniques to discover mapping rules between PEOs and SOs and correlation rules among SOs. As a case study, this paper demonstrates how association rule mining techniques is applied to discover PEO-SOs mapping rules and SOs correlation rules in engineering programs. To this end, a set of 152 self-study reports of engineering programs, accredited by American Board for Engineering and Technology-Engineering Accreditation Commission (ABET-EAC), have been collected and the mapping data between their PEOs and ABET-EAC SOs have been extracted. The dataset has been processed and transformed into a representation suitable for association rule mining techniques. This involves identifying a set of PEOs labels, annotating data instances with PEOs labels, and projecting each multi-label data instance into a set of single-label instances. Apriori algorithm is then applied to generate rules involving PEOs and SOs. The generated rules are then filtered to obtain mapping rules between PEOs and ABET-EAC SOs and the correlation rules among SOs. The filtered rules are then used to draw a set of generic rules for mapping each PEO to ABET-EAC SOs and to figure out potential correlations exist among ABET-EAC SOs.

1. INTRODUCTION

Outcome Based Education (OBE) [1] is a new educational system that focuses on graduate attributes which allow students to accept the challenges, adopt to technological changes, and translate their knowledge to new contexts for the benefit of the society. In this sense, OBE-based academic programs are designed to develop various abilities as per the requirements of graduate attributes. An

essential step in designing OBE academic program is the identification of long-term PEOs and SOs [2]. While SOs represent the knowledge, skills, and capabilities that students should possess by the time of graduation, PEOs represent the achievements graduates should attain few years (3 to 5 years and more) after graduation. Having specified the PEOs and SOs of an OBE academic program and established the mapping between them, the curriculum, teaching and learning strategies, and assessment strategies are then designed in such a way that students ultimately gain knowledge and develop skills stated in the SOs. In this manner, the curriculum is viewed as a set of courses aim to attain certain Course Outcomes (COs) that map to SOs which themselves map to PEOs which in turn map to the mission of the institution in a hierarchical structure shown in Figure 1.

Figure 1. Structure of OBE academic program [1]

Despite the crucial role of PEOs-SOs mapping, there is a consensus on the lingering confusion, among practitioners, related to them and how they are correlated to each other [3]. The drastic consequences of such confusion is a poor design of curriculum and teaching strategies and a misleading assessment of PEOs and ultimately inaccurate corrective plan. To this end, this paper proposes using Association Rules Mining (ARM) techniques [4] to inductively interrogate a set of PEOs-SOs mapping data. More specifically, this paper demonstrates an application of Apriori algorithm to a set of PEOs-SOs mapping data extracted from self-study reports (SSRs) of a number of engineering programs accredited by ABET-EAC. This results in a huge sets of rules which are further filtered to arrive at specific knowledge in a form of generic rules for mapping PEOs to ABET-EAC SOs and correlations rules among ABET-EAC SOs.

2. METHODOLOGY

The methodology of this work has been customized from the general methodology of the knowledge discovery process depicted in Fig. 2. It involves raw data collection, selection, preprocessing, transformation, mining, and evaluation [4]. In the data collection step, a raw data is collected and used to create a target dataset or focusing on a subset of variables or data samples on which discovery is to be performed. The target data is cleaned

Anwar Ali Yahya, Fekri Mohammed and Addin Osman "A Novel Use of Educational Data Mining to Inform Effective Management of Academic Programs" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 484 - 487

and preprocessed in order to obtain consistent data in the pre-processing step. The transformation step transforms the data using dimensionality reduction or other transformation methods. The step of data mining applies procedures to search for patterns of interest in a particular representational form, depending on the data mining objective. Finally, in the interpretation/evaluation step, the mined patterns are interpreted and evaluated.

A particular data mining techniques, which are applied to discover all hidden associations that satisfy some user-predefined criteria are association rules algorithms [5]. A widely used algorithm for the association rules mining is the Apriori algorithm [6]. It is based on the following rule: All sub-itemsets of a frequent itemset must also be frequent. Using this rule, Apriori algorithm prunes a huge amount of itemsets examinations since it is certain that they are not frequent. Frequent sub-itemsets are extended one item at a time (candidate generation), and groups of candidates are examined. It terminates when no further extensions are found.

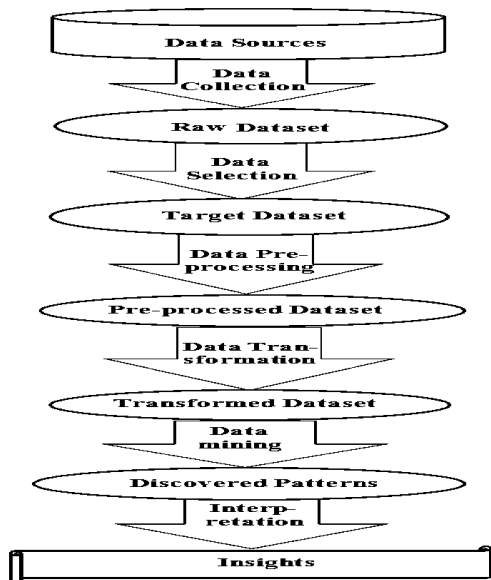

Figure 2. Knowledge Discovery Methodology

3. ARM OF PEOs-SOs DATA IN ENGINEERING PROGRAMS

3.1 Raw Data Collection

The raw data is a set of SSRs of 152 engineering programs [7] accredited by ABET-EAC between 2000 and 2017 and distributed over the years as in Figure 3.

Figure 3. SSRs distribution over years

3.2 Data Selection

The PEOs-SOs mapping data are extracted from sub-section B of the third criteria (Student Outcomes) of each SSR and

consolidated in a table form as shown in Table 1, where symbol ✓ (×) indicates the presence (absence) of the SO in the mapping with the PEO.

Table 1. Excerpts from PEOs-SOs mapping data

PEOs	a	b	c	d	e	f	g	h	i	j	k
Practice the disciplines of transportation, environmental, structural, water resources, and geotechnical engineering, and/or related fields.	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
Engage in advanced education, research, and development	✓	✓	✓	×	✓	×	×	×	✓	×	✓
Pursue continuing education and professional licensure	×	×	×	×	×	×	×	×	✓	×	✓
Act in a responsible, professional and ethical manner	×	×	×	×	×	×	×	✓	×	✓	×

3.3 Data Preprocessing

The preprocessing of the dataset involves substantial verification and validation of the content, attempts to remove spurious or duplicated objectives, fulfilling the objectives and outcomes format.

3.4 Data Transformation

A transformation procedure is proposed to transform each PEO into a set of labels representing attributes expressed in its text as follows.

3.4.1 PEOs Labels Set Identification

PEOs are grouped into a finite set of common attributes. Based on PEOs wordings of a number of engineering programs, a set of common PEOs labels has been proposed as shows in Table 2.

Table 2. PEOs Labels Set

No	PEOs Category	PEO Label	Frequency
1	Life-long Learning	LL	130
2	Communication	C	82
3	Leadership	L	62
4	Teaming	T	98
5	Ethical Conduct	EC	81
6	Professionalism	P	137
7	Social and Community	SC	78
8	Career Success	CS	127
9	Technical Competency	TC	212
10	Knowledge	KC	96
11	Graduate Studies	GS	64
12	Others	O	29

3.4.2 PEO Annotation

Each instance of PEOs-SOs mapping data is annotated with one or more labels that match its PEO text. Three annotators initially annotated the dataset individually. The three annotators then met to resolve the conflicting cases. Table 3 shows excerpts of the dataset after PEOs annotation. The symbol ✓(×) denotes the inclusion (exclusion) of a particular SO in the mapping.

Table 3. PEOs Labeled Dataset

PEOs Labels	a	b	c	d	e	f	g	h	i	j	K
TC	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓	✓
LL GS	✓	✓	✓	×	✓	×	×	×	✓	×	✓
LL P	×	×	×	×	×	×	×	×	✓	×	✓

3.4.3 Data Projection

Each multi-label data instance is projected into a set of single-label data instances by making a single copy for each PEO appears in the original data instance. This results in an enlarged dataset with 1196 single-label data instances. Table 4 shows the excerpts of Table 3 projection.

Table 4. Projected PEOs Labeled Dataset

P	×	×	×	×	×	×	×	×	✓	×	✓

3.5 Association Rules Mining Application

Apriori algorithm is applied under WEKA framework [8]. It works by iteratively generating the frequent k-item sets whose their count equal to or greater than a pre-specified minimum support count, which is calculated as in Eq. 1

$$support(PEO \Rightarrow SOs) = \frac{count(PEO \cup SOs)}{N} \quad (1)$$

Then in the rules generation, rules that satisfy the user specified confidence threshold is generated. The confidence level of the rules is calculated using Eq.2

$$confidence(PEO \Rightarrow SOs) = \frac{count(PEO \cup SOs)}{count(PEO)} \quad (2)$$

In this research the minimum support and minimum confidence are set to low values, 0.1, to generate as many rules as possible.

3.6 Evaluation

The application of Apriori algorithm results in a huge number of rules, therefore, the generated rules are then filtered and interpreted to extract useful insights.

3.6.1 PEOs-SOs Mapping Rules

The generated rules are filtered to extract PEOs-SOs mapping rules. These rules are characterized by having a particular PEO in its antecedent and a combination of SOs in its consequent. The filtered rules are then sorted based on their confidence and the top-10 rules are presented in Table 5.

Table 5: Top-10 PEOs-SOs mapping rules

Using the top-10 rules for each PEO, a more generic representation can be obtained as shown in Table 6. In this Table the symbols ✓, ×, and ? indicate, respectively, the presence, absence, and undetermined state of a given SO in the consequent of the PEO rule. It can be observed that the *Ethical Conduct* and *Social and Community* PEOs (*EC* and *SC*) have the highest average confidence, whereas *Knowledge Competency* and *Graduate Studies* PEO (*KC* and *GS*) have the lowest. Moreover, it can be observed that the *Social and Community* and *Knowledge Competency* PEOs (*SC* and *KC*) are not dependent on the presence of any SOs. They mainly depend on the absence of different combinations of SOs. The *Lifelong Learning*, *Communication*, *Ethical Conduct*, and *Professionalism* PEOs (*LL*, *C*, *EC*, *P*) depend on the presence of a single SO, which indicates a one to one mapping between the graduate attribute of the PEO and the skills of the SO.

Table 6. Recommended PEOs-SOs mapping

3.6.2 ABET-EAC SOs Correlations Rules

In order to discover correlations among ABET-EAC SOs, the generated rules are filtered to extract rules of the form $SOx \Rightarrow SOy$ and $\bar{SOx} \Rightarrow \bar{SOy}$, where SOx and SOy are two given SOs. Table 7 shows the extracted rules along with their confidence values. The correlation between SOx and SOy is defined in terms of the confidence in their equivalency as follows

$$Correlation(SOx, SOy) = Confidence(SOx \Leftrightarrow SOy) \quad (3)$$

$$= Confidence((SOx \wedge SOy) \vee (\bar{SOx} \wedge \bar{SOy})) \quad (4)$$

$$= P((SOx \wedge SOy) \vee (\bar{SOx} \wedge \bar{SOy})) \quad (5)$$

$$= P(SOx \wedge SOy) + P(\bar{SOx} \wedge \bar{SOy}) \quad (6)$$

$$= P(SOx | SOy) \times P(SOy) + \bar{SOx} | \bar{SOy} \times P(\bar{SOy}) \quad (7)$$

$$= Confidence(SOx \Rightarrow SOy) \times P(SOy) + Confidence(\bar{SOx} \Rightarrow \bar{SOy}) \times P(\bar{SOy}) \quad (8)$$

By applying Eq. 8 to the data of Table 7, the correlations among ABET-EAC SOs pairs can be calculated and a correlations graph can be depicted as shown in Figure 4, where 0.65 is assumed as a minimum confidence for drawing a link between PEOs pairs. This threshold value allows each PEO to be linked to at least one PEO. In the correlation graph, the thicker the link is, the stronger the correlation between PEOs is.

Figure 4. ABET-EAC SOs correlations graph

Obviously, three SOs clusters appear in the correlation graph. The first cluster involves *technical skills* SOs (a, b, c, e, and k). The second clusters involves *process skills* SOs (d and g), and the third cluster involves *awareness skills* SOs (f, h, i, and j).

4. CONCLUSION

Association rules data mining techniques is proposed to discover useful insights on the rules that govern the mapping between PEOs and SOs and the correlations among SOs of academic programs. The discovered insights are useful for academicians to manage academic programs. In addition, a number of interesting correlations between PEOs and ABET-EAC SOs and among ABET-EAC SOs themselves have been discovered.

ABSTRACT

Predictive and data-intensive modeling has rapidly gained prominence in many research fields over the past decade. In recent years, the fairness of analytical models has become an increasingly important question for researchers: might a model systematically underperform on certain demographics? Might its application have different impacts across different demographic groups? Recently, these questions have found their way into educational research as well, where predictive and statistical modeling is used for such purposes as predicting course completion, assisting university recruitment, and proactively offering assistance to students. If such models are potentially unfair, students may remain underserved or suffer potential harm as a result. In this paper, we demonstrate two post-hoc assessments of fairness, applied to existing models predicting student graduation. Our assessments are intended to check for, rather than proactively prevent, algorithmic bias in predictive models. The first assessment investigates whether a selected model is *equitable*: does its performance systematically differ for members of different demographic groups? The second investigates whether the decision to use one model for all individuals in a given dataset is *optimal*: does using one model for all students come at a significant loss in per-group accuracy? By assessing fairness systematically, we hope to reduce to the risk of inequities from predictive analytics in education.

1. INTRODUCTION

As educational research incorporates more automated tools for analyzing and predicting such factors as student behaviors and educational outcomes, the field must grapple with the ethical question of algorithmic fairness. Do our algorithms, powerful as they may seem, encode and reinforce existing societal inequalities? Are the predictive tools we use systematically less accurate for some demographics, and does the use of these tools risk harming members of those demographics?

In this work, we assess a set of machine learning models,

trained to predict student graduation at a public, four-year university, using several definitions of fairness. Our analysis centers on race and gender, but in principle, can be extended to include age, international status, or other categorical variables.

Our investigations are driven by two main research questions: RQ 1) Are the models *equitable*? Do they perform considerably worse on students of particular genders or ethnicities? RQ 2) Are the models *optimal*? Could we achieve substantially better accuracy by using models specific to particular genders or ethnicities?

We investigate these questions through comparisons of false positive rates, false negative rates, and overall accuracy measures, since these each represent different potential impacts of these models' use. The primary intended use of the models is to aid university advisers, and faculty, and administrators in structuring student support. This intended use of the models informs our particular definitions and questions around the fairness of these models.

2. RELATED WORK

Researchers have utilized a wide range of approaches to defining fairness. Dwork et al. [4] define fairness as *similar individuals receive similar predictions* (individual fairness). Hardt et al. [7] measures *equalized odds*, which penalizes models for performing well only on the majority of data points, and *equal opportunity*, which requires parity between groups' predictions only where the ground truth is an "advantaged" outcome (e.g., "was admitted to college," "received a promotion"). Feldman et al. [5] propose measures of *group fairness*, where the distribution of errors and impacts should not vary across groups. There are many approaches to controlling for these, and other, fairness measures, as discussed in, e.g., [2, 9].

While the exact definitions and approaches to fairness are quite varied, a common thread is that there are no unambiguously "correct" definitions of fairness, or clear ways to control for all aspects of it. The particular definitions and measures depend on the specific data, analysis, and use case.

3. FAIRNESS FOR OUR MODELS

We select our measures of fairness based on the intended applications of the models, and their potential impact. The models are intended to inform and assist advisers, mentors, faculty, and university administrators in making decisions

Henry Anderson, Afshan Boodhwani and Ryan Baker "Assessing the Fairness of Graduation Predictions" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 488 - 491

about student intervention, student support, and university policies. We focus on the advising and mentoring applications, as this is the first intended use for the models.

In this setting, we anticipate a difference in the impacts of false negative and false positive errors. False negatives (students on track to graduate who are identified as likely to not graduate) are likely to result in additional contact with advisers, and additional assistance being made available. There is little harm to the student. False positives (students not on track to graduate, but who are predicted as likely to graduate) mean a student may not receive assistance from advisers. The potential harm is much greater. We thus use both false positive and false negative rates as metrics for fairness, per RQ 1, but we are more concerned with possible disparities in the false positives.

The overall accuracy of the models may also vary across our populations. Large variations put certain populations at higher risk of being systematically underserved due to lower-quality predictions, and thus less reliable information being presented to advisers and mentors. Therefore we test if selecting one model, trained on all students, is optimal, per RQ 2, by comparing its overall accuracy to the population specific models.

4. DATA

In this paper, we assess the fairness of models predicting whether a student will graduate within six years, initially presented in a conference poster [1]. In this section, we briefly describe the data on which those models were trained; more details are available in the original presentation.

The dataset utilized was from a large, publicly-funded, R1 research university in the southern United States. It contains data on 14,706 first time in college (FTIC) undergraduate students, all of whom were admitted in Fall semesters between 2006-2012 (inclusive), and were enrolled full-time. The data contains one entry per student, summarizing their first three enrolled semesters (Fall, Spring, and Summer). The final feature set covers academic performance (e.g. GPA, credit hours completed), financial information (e.g. scholarships, unmet need), pre-admission information (e.g. SAT/ACT scores), and extra-curricular activities (e.g. Greek Life, athletics). A student's first year has been shown to be an important period for determining a student's likelihood of dropping out [8], which while not quite the inverse of graduation, is a closely related outcome.

Tables 1 and 2 shows basic descriptive statistics for the dataset. Some of the populations have very small N s. We include these populations in the fairness analyses for completeness, but we caution against drawing meaningful conclusions from them. Similarly, we caution against drawing conclusions for the Multiple Ethnicities and Foreign populations, since these are "catch-all" labels, and represent extremely diverse groups of students.

5. METHODOLOGY

5.1 Model Building

We investigate the fairness of five separate models, each trained on our dataset to predict whether a student will

Table 1: Basic descriptive statistics of the dataset, by self-reported ethnicities.

Population	N	Graduation rate
American Indian	44	27.27%
Asian	2091	61.74%
African American	2092	38.48%
Foreign	296	52.03%
Hispanic/Latino	3805	43.97%
Multiple Ethnicities	499	48.30%
Hawaiian/Pacific Islander	22	54.55%
Ethnicity Not Specified	85	35.29%
White	5772	44.51%
TOTAL	14706	46.15%

Table 2: Basic descriptive statistics of the dataset, by self-reported gender.

Population	N	Graduation rate
Female	7613	50.06%
Male	7092	41.96%
Gender Unknown	1	0.00%
TOTAL	14706	46.15%

graduate within 6 years of first enrolling at the university. Early versions of these models (except Random Forest) have been presented in poster form [1]: linear kernel Support Vector Machines (SVM), Decision Trees, Random Forests, Logistic Regressions, and scikit-learn's Stochastic Gradient Descent classifier (SGD¹).

Each model was trained on 80% of the full dataset, with 20% held out for testing. The train-test split was conducted such that the proportions of students in each demographic category were as close as possible across the folds, and the within-group and overall graduation rates were as similar as possible. Model parameters were selected using 5-fold cross-validation within the training set. Ethnicity and gender features were omitted when training the models.

5.2 Assessing Equity

We measure the equity of our models via their false positive and false negative predictions on the held-out testing set. Each comparison is made using a one-versus-rest approach: *Male* versus *non-Male*, *White* versus *non-White*, etc. To compare false positive and false negative rates, we assign each student a label of 1 (indicating a false positive/false negative prediction) or 0 (true positive/true negative). The populations are compared using a χ^2 test on the resulting binary-valued vectors, with Benjamini & Hochberg's post-hoc correction [3] applied within each combination of population and fairness metric, across algorithms.

¹scikit-learn's `SGDClassifier` model uses gradient descent to construct a hyperplane classifier. We refer to this classifier, not the general numeric optimization method, in this paper. See the scikit-learn documentation for further details: <https://scikit-learn.org/stable/modules/sgd.html>

Table 3: Results of the χ^2 tests on false negatives and false positives, by demographic. Differences shown are the overall rates for students in the listed demographic, minus the overall rates for students not in the listed demographic. Benjamini & Hochberg [3] corrected p -values are in parentheses; p -values less than 0.05 are in bold. * = $N < 500$.

Table 4: Model scores, trained on all students, evaluated against the held-out testing set. Values in parentheses are the standard error, calculated as in [6].

Model	AUC
Decision Tree	0.798 (0.008)
SVM	0.805 (0.008)
Logistic Regression	0.807 (0.008)
Random Forest	0.800 (0.008)
SGD	0.814 (0.008)

5.3 Assessing Optimality

To assess the optimality of our models (RQ 2), we compare how much accuracy is gained or lost by building separate models for each population, based on AUC ROC scores. For each population in our dataset, we compare the AUC ROC scores (calculated only on the test set) of the models when trained on all students to the AUC ROC scores of the models when trained only on that population.

6. RESULTS

6.1 Model Performance

The overall metrics, evaluated against all students in the testing set, are reported in Table 4. The models achieve consistently good performance, with high AUC ROC and F1 scores. These numbers are a good baseline of performance; if the models’ performance drops or rises considerably for any demographic, that can be taken as an indication of algorithmic bias and the need for population-specific models. AUC ROC standard errors are computed according to Hanley & McNeil’s method [6].

6.2 RQ 1: Model Equity

Table 3 shows the results of our investigation into RQ 1. The majority of the comparisons do not show significance at $p = 0.05$ after correction. Notable exceptions are White students, with consistently higher false positive and lower false negative rates across all models; Hispanic/Latino students, with consistently higher false negative rates for the tree-based models; and Male students, who have consistently higher false negative rates for hyperplane-based models (SVM, SGD, and Logistic Regression).

Since the impacts of false positives are likely to be more harmful than false negatives, we find the consistently higher false positive rate for White students to be more noteworthy than the false negative results.

6.3 RQ 2: Model Optimality

Table 5 shows the AUC scores and AUC standard errors on each population for two models: one trained on the entire dataset and tested only on students in the listed demographic group (“Whole Population Model”), and one trained only on students in the listed demographic group (“Population Specific Model”). The only instance where the performance differed by more than the standard error is the Logistic Regression model for Asian students, which saw a *decrease* in performance when using the population-specific model. This indicates that the current models are optimal in terms of population-specificity: population-specific models do not gain appreciable predictive power for any population in the dataset.

Further, this indicates that the trends identified by the models generalize across populations in the dataset, and thus, the models’ performance on all students benefits from access to

Table 5: The results of comparing the AUC ROC scores for models trained on all students (“Whole Population Model,” abbreviated “WPM”) versus just one demographic (“Population Specific Model,” abbreviated “PSM”). AUCs with non-overlapping standard error (SE) intervals are in bold.

Population		DT		RF		SVM		LR		SGD

the full population at training time. However, since the models primarily identified GPA and student credit hours obtained as the most important predictors [1], this trend may be specific to these variables.

7. DISCUSSION AND FUTURE WORK

We have demonstrated an approach to assessing fairness that derives definitions of fairness directly from the use cases of the models in question. We find that our models are not perfectly equitable, as the term is defined in RQ 1. However, the differences are generally small (under 5%), and with the important exception of White students, are not consistent across all models. We encourage any end-users of models that display some unfair tendencies to be cautious and mindful of the potential impact. These differences are relatively small, but it has still not been established what level of unfairness should be considered acceptable in a model with real-life implications. Perfect fairness is ideal, but difficult to achieve. Our models are, though, very optimal across groups, in terms of our definition in RQ 2. No model, or population, saw a meaningful change in per-group performance when trained only on one population.

The most important avenue for future work on this subject is investigating how the implementation of models such as these (e.g. making them available to advisers) will affect student outcomes, and whether the slight unfairness observed here will translate to real-world differences. The assessment of fairness we have performed is an attempt to pre-empt such effects, but is not a substitute for directly measuring them.

ABSTRACT

Research has shown that participating in online discussion forums is tied to improved learning outcomes, but in the case of Massive Open Online Courses (MOOCs), very few students utilize this resource. This paper presents a preliminary investigation of demographic differences in the relationship between participation (using four different measures related to students production in the forum and the responses they receive) and course completion, demonstrating the need of further research into the potential causes for these differences.

Keywords

MOOC, MORF, demographic analysis, gender, race, production rules

1. INTRODUCTION

As educators seek to better support students in Massive Open Online Courses (MOOCs), research has shown that participation in MOOC discussion forums is tied to completion rates as well as other measures of learning [4, 9, 21, 26]. However, within the same body of research, we find that the vast majority of students never post even once [20].

These low rates of participation are perhaps not surprising. In addition to factors that can make it difficult for, say, a working adult to commit to a course [13], issues surrounding the social practices of both learning and language make the sheer size of a MOOC discussion forum difficult for people to navigate [2, 19]. Some researchers, concerned about the importance of having a social presence (see [22]) in online learning, have even suggested that we try to facilitate the community structure by encouraging MOOC participants enroll with a cohort of friends (e.g., [6]).

In addition to the social factors that influence motivation, encouraging students to enroll with friends may also improve students' opportunities to learn by giving them the opportunity to speak (or write) with people who use familiar communication practices. For example, we know that cultures differ in terms of several language practices that are likely relevant to learning contexts, including appropriate manners for giving advice [29], request strategies [30], expressing disagreement [31], including

outsiders in the conversation [14] and even the interpretation of silence [10]. We also know that these differences can lead to cultural differences in broader interpretations of politeness (e.g., [7, 23]), and that sometimes these differences are even found across dialects of the same language (e.g., [18]) or across demographic groups, especially gender, within the same dialect (e.g., [17]).

Research on demographics in MOOCs has found that they can influence the level of student participation. For example, Huang et al. [11] found different rates of postings based on nationality and gender, with men posting more frequently than women and students from some countries posting at much higher rates than those from other countries. Likewise, Hodgson & Hui [12] also found differences based on nationality, with Chinese students posting at higher rates than those from other countries.

This study builds on these previous findings, exploring the role of demographic differences (namely race and gender) within the MOOC Replication Framework (MORF) [5]. Specifically, we are interested in two questions: 1) How do previous findings on forum posting behaviors and their relationship to course completion replicate across multiple MOOC sessions when broken down by reported gender and race? 2) Are these replications significantly different by race and gender?

2. METHODS

This research was conducted within the MOOC Replication Framework (MORF) [5], a platform designed to enhance large-scale replication efforts by representing previously published findings as production rules. In order to accomplish this, MORF uses a simple formalism that was previously employed in work to develop human-understandable computational theory in psychology and education [3, 16]. This approach allows findings to be represented in a fashion that human researchers and practitioners can easily understand.

All findings are converted into if-else production rules following the format, "If a student who is <attribute> does <operator>, then <outcome>." Attributes are pieces of information about a student, such as gender or race. Operators are actions a student does within the MOOC. Outcomes can represent a number of indicators of student success or failure including watching a majority of videos (e.g., [15, 24]) or publishing a scientific paper after participating in the MOOC (e.g., [26]). In the current study, we focus on the platform's most commonly-studied student outcome: whether or not the students in question completed the MOOC.

Each production rule analysis returns two counts: 1) the confidence [1], or the number of participants who fit the rule, i.e., meet both the if and the then statements, and 2) the

Juan Miguel Andres-Bray, Jaclyn Ocumpaugh and Ryan S. Baker "Hello? Who is posting, who is answering, and who is succeeding in Massive Open Online Courses" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 492 - 495

conviction [8], the production rule’s counterfactual, i.e., the number of participants who match the rule’s then statement but not the rule’s if statement. For example, in the production rule, “If a student started more threads than the session average, then they are more likely to complete the MOOC,” the two counts returned are the number of participants that started more threads than the average and completed the MOOC, and the number of participants who started threads less than the average, but still completed the MOOC. As a result, for each MOOC, a confidence and a conviction for each production rule can be generated.

A chi-square test of independence can then be calculated comparing each confidence to each conviction. The chi-square test can determine whether the two values are significantly different from each other, and in doing so, determine whether the production rule or its counterfactual significantly generalized to the data set.

In this study, we tested the replicability of four previously published findings on discussion forum posting behavior, which can be put into two categories: initiating discussion and receiving uptake of discussion. The previously published findings can be found in Table 1 as production rules. These production rules use normalized measures of students forum activity (i.e., higher or lower than average) to investigate who is responsible for starting the most threads, posts more often overall, who gets more respondents on their own threads, and who posts more responses to others’ threads.

Table 1. Categories of production rules used in the study

Condition	Source
Initiating Discussion:	
• If the student started more threads than the session average (Threads)	[4]
• If the student posts more frequently than the session average (Posts)	[9, 28]
Receiving Uptake of Discussion:	
• If the student has more respondents on their own threads than the session average (Respondents)	[21]
• If the student has more responses than the session average (Responses)	[27]

Note. The THEN clause of each production rule states, “then they are more likely to complete the course and earn a certificate.”

These findings were turned into production rules, and executed in MORF against its data store of 100 MOOC sessions, comprised of 45 different courses offered by a University on Coursera. In integrating across MOOCs, we choose the conservative and straightforward Stouffer’s [25] Z-score method to combine the results per finding across the multiple MOOC data sets, which we used to obtain a single statistical significance result across all MOOCs per reported gender and race.

Stouffer’s Z-score method was used to compare resulting Z-scores across both genders and across the four races included in the study: White or Caucasian, Black or African American, Asian, and LatinX. In this study, we included only students who

had reported their gender or their race in Coursra’s optional demographics survey. Furthermore, only students from the U.S. were included in order to avoid complications of racial/ethnic categories that do not always translate in a straightforward manner across national boundaries. Table 2 summarizes the number of students in each category.

Table 2. Summary of research subjects by race and gender categories; all included reported being U.S. students

Demographic	N
Female	10,813
Male	14,394
White or Caucasian (W)	12,802
Black or African American (B)	1,089
Asian (A)	5,299
LatinX (L)	3,960

3. RESULTS

3.1 Gender Differences

The relationship between gender and the four discussion forum conditions included in this study can be found in Table 3. Each row represents the result of testing that condition, or MORF production rule, across the full set of MOOCs, reported by gender. For example, “Posts” refers to the production rule, “If the student’s total number of posts was higher than the session average, then they are more likely to complete the course and earn a completion certificate.” The *Female* and *Male* columns list the cumulative Z-scores per reported gender, and can be interpreted as how well each rule replicated across MORF’s data. The *Diff* column lists the resulting Z-score when comparing whether the *Female* and *Male* scores are significantly different.

Table 3. Results of production rule analysis and gender differences in posting behavior (* $p < 0.001$)

Feature	Female	Male	Diff
Threads	16.36*	26.57*	7.22*
Posts	19.66*	29.89*	7.23*
Respondents	15.19*	21.69*	4.60*
Responses	14.60*	19.29*	3.32*

As seen in Table 3, all four production rules replicated significantly across all MOOC sessions in both genders. That is, thread, posts, respondents, and responses conditions all show positive relationships with MOOC completion. Moreover, as the *Diff* column shows, the positive relationship between forum participation and course completion is significantly more likely to replicate on men than women across all four measures.

3.2 Racial Differences

The relationship between race and the four discussion forum conditions included in this study can be found in Tables 4 and 5. In Table 4, each row represents the result of testing each production rule across the full set of MOOCs, broken down by reported race. As in Table 3, the *Feature* column lists the

important key words of the rule's IF statement, and the other columns list the cumulative Z-scores per reported race. Like in Table 3, these values can be interpreted as significance values of how well each rule replicated across MORF's datasets. Table 4 shows that all four production rules replicated significantly across all MOOC sessions in all reported races included in this study.

Table 4. Results of production rule analysis broken down by reported race (* $p < 0.01$, ** $p < 0.001$)

Feature	White	Black	Asian	LatinX
Threads	19.57**	4.58**	8.67**	8.64**
Posts	22.78**	3.59**	9.42**	8.58**
Respondents	14.73**	3.12*	8.18**	7.11**
Responses	14.31**	4.27**	8.11**	6.31**

Table 5 reports the differences by race in the resulting Z-score. Here, it is important to note that the racial category listed first is the category with the higher Z-score value. As the table shows, nearly all of the comparisons were statistically significant, with notable exceptions found primarily in the comparison between Asian and LatinX students (the final column), although the difference between LatinX students and Black/African American students also had one condition (responses) that was not significant.

Table 5. Racial differences in posting behavior; W = White or Caucasian, B = Black or African American, A = Asian, L = LatinX (* $p < 0.01$, ** $p < 0.001$)

Feature	W>B	W>A	W>L	L>B	A>B	A>L
Threads	10.6**	7.7**	7.7**	2.9*	2.9*	0.0
Posts	13.6**	9.5**	10.**	3.5**	4.1**	0.6
Respondents	8.2**	4.6**	5.4**	2.8*	3.6**	0.8
Responses	7.1**	4.4**	5.7**	1.4	2.7*	1.3

4. DISCUSSION & CONCLUSIONS

In order to interpret these results, it is useful to consider the semantics of these conditions, two of which (posts and threads started) look at the initiation of discussion, measuring a student's production of discussion posts and two of which (respondents and responses) measure the uptake a student receives from those in his or her cohort. Our results show all four production rules significantly replicated across all MOOC datasets, and these findings are consistent no matter the demographic category considered.

At the same time, these results show that there are demographic differences both in who chooses to post and in whose posts receive the most attention. Namely, men are more likely than women to complete the course and earn a certificate based on initiating discussion and receiving uptake, results which may, in fact, influence one another.

We found the same kind of discrepancies when we looked at racial categories. Specifically, White/Caucasian students were more likely to succeed in MOOCs based on posting and receiving uptake than any other racial category. However, while Asian or LatinX students were more likely to succeed than

Black/African American students based on forum behavior, the magnitudes of these differences were smaller than those between White/Caucasian students and other categories. Finally, Black/African American students were the least likely to succeed across all four measures.

More research is needed to better understand what might be causing these communication differences, but this preliminary study highlights the importance of examining these differences, as it shows they are important factors for predicting student success in MOOC platforms. If demographic differences exist at this level of analyses, it is likely that sociocultural strategies related to politeness or other communication practices are at play.

In future work, we hope to offer more sophisticated analyses of these issues, explicating the specific practices that may be contributing to these disparities. However, in the meantime, we hope this preliminary work serves to demonstrate a potential importance of these considerations when trying to support online learning.

Augmenting Transcripts with Natural Language Processing and Multimodal Data

Tyler Angert

bertrand_schneider@gse.harvard.edu

ABSTRACT

In this paper we explore preliminary applications of augmenting transcripts with multimodal data. In a previous study, pairs of participants (dyads) learned how to program a robot to navigate a maze using a block-based programming language. As the dyads completed the task, their transcripts and various multimodal data were captured, creating a synced dataset of speech, 3D motion capture points, electrodermal activity, heart rate, and eye tracking. In this paper, we describe a simple visualization method to more easily analyze conversation during collaboration: a “Convergence chart” which visualizes changes in biometrics between speakers throughout a conversation. These visualizations allow researchers to see high level trends in transcripts by using a combination of Natural Language Processing (NLP) and physiological data to generate new insights on how collaboration changes over time. We conclude with how to use these visualizations to create new metrics to understand group dynamics.

Data Visualization, Computer Supported Collaborative Learning, Natural Language Processing, Biometrics

1. INTRODUCTION

Transcripts are one of the most common forms of recording speech and are a cornerstone of qualitative data analysis. With the increase of labeled text data sets and machine learning techniques, various data visualization applications have made text and conversations easier to analyze. However, transcripts often ignore a significant amount of context from conversation such as body language, tone, shift in conversation topic, eye movements, physiological changes and physical actions. Consequently, most transcript visualization methods fail to provide adequate context for how conversation changes over time. More importantly, because it is becoming easier to collect large multimodal datasets, researchers have an open space to improve how we use multimodal data to enrich textual analysis.

2. LITERATURE REVIEW

2.1 General theoretical Framework

The theoretical framework for this paper comes from theories of collaborative learning, which has been one of the main topics of interest in the Learning Sciences over the last decades. In this paper, we focus on Roschelle’s [4] framework of convergent conceptual change. In this framework, collaboration is seen as the process of constructing shared meanings for conversations, concepts and experiences. This process has been extensively studied from a psycho-linguistic perspective and is referred to as grounding [5]. Building a common ground ensures that collaborators are on the same page and share a common definition of the terms used. From this perspective, grounding allows group member to anticipate and prevent misunderstanding. We use this framework as a foundation for the visualizations presented below: our hypothesis is that convergent conceptual change is punctuated by increased levels of synchronization between participants across various metrics (e.g., not just in terms of the words used, but also in terms of additional text features and multimodal indicators). The visualizations below provides a first step toward exploring how collaboration unfolds over time through a variety of metrics.

2.2 Augmenting Transcripts with Natural Language Processing and Multimodal Datasets

This paper relies heavily on previous work done in Natural Language Processing (NLP), conversation analysis, social network analysis, data visualization and Multimodal Learning Analytics (MMLA) [6]. We discuss the shortcomings and insights from related literature and how using multimodal data in transcript visualizations can be useful to generate new insights about collaborative learning. In particular, previous studies have used focused on for evaluating social dynamics in conversations with basic NLP data. For example, Viegas and Donath [1] found that using simple abstract shapes like circles and rectangles could easily reveal underlying patterns in online conversations like lurking, inactive users, and people who dominated conversations, all of which contributed to creating “a snapshot of an entire conversation in one image.”

However, relatively few studies combine NLP and biometric data directly into the visualization of dialogue. We propose that augmenting traditional data visualization techniques with multimodal data can make conversation analysis more efficient and form a foundation for future multimodal data visualization for use in other fields. In the next section, we describe the visualization methods we designed and provide specific examples

from the dataset that help us identify metrics that differentiate between productive from less productive groups.

3. METHODS

3.1 Description of the dataset

Random pairs of participants with no self-reported prior programming or robotics knowledge were tasked with programming a robot to solve a series of increasingly complex mazes in 30 minutes. Mobile eye-trackers recorded participant gaze data, bracelets captured electrodermal activity (EDA), and a motion sensor collected movement and position data. Four physiological synchrony measures were calculated for movement and EDA data: Signal Matching (SM), Instantaneous Derivative Matching (IDM), Directional Agreement (DA) and Pearson's Correlation (PC). For a description of these metrics, see [7]. All speech and verbal interactions were transcribed and labeled with timestamps. Through a series of pre processing techniques, the transcripts, gaze data, and EDA data were all aligned along each transcript timestamp. In order to compensate for the higher frequency of data from the sensors relative to the transcripts, we took the average of all of the sensor values from after each transcript line began to an ending point based on an estimated words per minute (WPM) measurement based on the average amount of time each participant spoke.

We collected three dependent measures: learning gains, collaboration quality and task performance. Learning gains were measured through a pre and post-test assessing the participants' understanding of computational concepts used in the activity. Collaboration was assessed on nine scales: sustaining mutual understanding, dialogue management, information pooling, reaching consensus, task division, time management, technical coordination, reciprocal interaction, and individual task orientation. Task performance was assessed through the quality of the final code produced by the dyad. For more information about these metrics, see [7].

For each of the transcripts, a series of basic linguistic measures were taken to serve as a baseline to compare transcripts. We hypothesized that certain linguistic features would help guide analysis of collaboration, such as word count, for past, present, and future verb usage count, singular and plural pronoun usage count, question count, and exclamation count.

Figure 1: Example of a standard setup for two participants learning to program the robot to complete the maze tasks.

To obtain a general overview of the topics spoken for each dyad and to add more depth to the visualizations, we ran Latent Dirichlet Allocation (LDA), a topic clustering algorithm, on all of the compiled transcript lines. In order to clean the data set, we removed "stop-words" from each transcript line (e.g. "a", "the", "and"), and any speech from the facilitator of the experiment. All natural language processing was done using the Python *Gensim* and *NLTK* libraries. The following topic clusters' *top words* (TW) were calculated along with a *possible theme* (PT):

1. **PT: Analysis.** TW: **Think, need, get**, else, got, really, something, block, good, second
2. **PT: Brainstorm.** TW: **Maybe, see, try**, one, put, wait, know, want, time, could
3. **PT: Sensors / actuators.** TW: **Sensor, one, two**, motor, right, four, greater, talk, three, know
4. **PT: Adjustment.** TW: **Make, sure, know**, yes, hundred, start, sense, value, function, sorry
5. **PT: Coding.** TW: **Turn, right, go**, forward, left, want, stop, going, need, wall

3.2 Data Visualizations

To understand how we conversations change relative to biometric signals, we created a visualization to study how subjects' physiological metrics align with each other with a *Convergence chart*. In order to create the visualizations, we created a custom web-based interface that allows us to dynamically manipulate the transcript data, compare groups, and adjust the parameters of the visualizations.

The basic visualization concept behind the Convergence chart is "shifting the conversation" closer to the center as both speakers' biometrics begin to align. Below is an image that describes the concept of the visualization:

Figure 2: Schematic of the Convergence chart. Each line in the transcript is represented by a colored block.

As the participants converge towards some biometric, e.g. begin to look at the same area of a computer screen (indicating Joint Visual Attention), the transcript blocks shift closer to the center. If the participants are looking at different areas of a computer screen, the transcript blocks will diverge away from the center. We chose Joint Visual Attention (JVA) as our primary metric to analyze. JVA measures when two participants are looking at the

same area at the same time and is significantly correlated with collaboration quality [2]. We also used Signal Matching (SM) and Directional Agreement (DA) from the electrodermal data as convergence metrics [3]. SM and DA capture physiological synchrony, i.e., when two participants increase or decrease their physiological arousal at the same time. The plot moves closer to the center based on how “far away” each speaker is from a reference metric. E.g., if the metric is JVA, then each transcript block will shift towards the chart center based on how close the group’s JVA value at that timestamp is to the *average of the maximum JVA across all groups*. Global measures allow us to compare groups relative to a summarized metric. We can also choose to observe local metrics where each chart is plotted according to the five-number summary of JVA values *within* each group. The reference metric can be any metric that describes the state of the dyad, not the individual participants.

Figure 3: JVA convergence chart for Group 15 (lowest collaboration) and Group 8 (highest collaboration). Colored by topic distribution.

When we inspect closer into the JVA chart, we can glimpse into the topics and specific quotes of the conversation. Because the visualization is combined with the colored topic distributions, we gain much richer insight into *who* is speaking when JVA is highest, *what* they speak about, and the surrounding context.

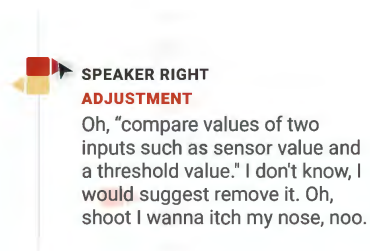

Figure 4: Focused transcript analysis from Group 15 and 8, respectively.

When we zoom out to observe patterns in larger chunks of the conversation, we can see that Group 15’s participants often take turns talking about predominantly one topic.

Figure 5: Conversation chunk analysis from Group 8.

Similar patterns emerge while analyzing other physiological synchrony metrics, like Directional Agreement (DA) and Signal Matching (SM) in the charts in Fig. 6.

Figure 6: SM and DA convergence charts, respectively, for Group 15 (lowest collaboration) and Group 8 (highest collaboration). Colored by topic distribution.

A primary trend emerges from these charts. Even across different physiological metrics, more productive groups tend to converge towards the center of the chart more frequently than less productive groups. Researchers can consequently see conversation trends relative to attentional and physiological synchrony. These trends imply that finding the most dominant topic chunks of a conversation could correlate with or predict changes in physiological metrics.

4. DISCUSSION

The preliminary results of these visualizations illustrate the benefits of augmenting transcripts with multimodal data and topic modeling algorithms. In particular, we found that these visualizations can distinguish productive groups from less productive groups in terms of overall collaboration-related metrics on our dataset. The insight for using these graphs as a heuristic to analyze collaboration in group is simple: productive, collaborative groups' conversations will converge together more towards physiological metrics. With the Convergence chart, we see that more productive groups speak about more similar topics during periods of high JVA than less productive groups. Productive groups behaviors appear more consistent and "focused" during periods of high physiological synchrony. We believe these observed differences relate much more to broader patterns during larger chunks of conversations rather than more granular, line-by-line analysis of transcripts.

5. LIMITATIONS

These visualizations have several limitations. The current methods are only applicable to conversations with exactly two people, i.e. when dialogue is the primary method of communication. While it is possible to extend the metrics produced by the chart into more than two dimensions, new visualizations would have to be created in order to visualize actions between multiple parties in the same conversation. Further, the Convergence chart condense nearly 30 minutes of dialogue and sensor information into one graphic, which makes large or dense conversations hard to view without a large display.

6. FUTURE WORK

Our methods bring up some interesting questions about conversation and dialogue that we can hopefully answer with new metrics, in particular determining how quickly conversations change, what causes change in conversation, and how conversations progress over time.

Some ideas for answering these questions involve calculating new metrics from the visualizations, including *the comparison metric*, *comparison value*, and *the percent each transcript line converges towards the center*. Using these newly constructed data sets, supervised machine learning models could be created to predict how speech and topics could change over the course of these conversations based on changes in physiological metrics. In the future, we plan on enriching our visualizations and analyses with Coh-matrix, which provide more in depth NLP analyses of text with measures such as lexical diversity and cohesion. It would also be possible to create a general framework for auto-generating Convergence charts given multimodal dataset. We will also evaluate the visualizations' effectiveness across several domains.

7. CONCLUSION

This work provides two significant contributions. First, we developed a new visualization method to analyze conversations and augment transcripts with multimodal data. We believe that researchers can take advantage of these methods to discover high-level patterns in other transcripts and textual data sets. Second, we showed that these visualizations can potentially serve as a baseline for creating new metrics to analyze conversations, dialogue, and collaboration. We hope that the work in this paper can encourage future work on combining multimodal data with textual data visualization to enrich conversation and collaboration analysis. We see learning analytics and data mining methods as a way to bridge the gap between qualitative and quantitative research. There is an opportunity to augment both strands of research through multidisciplinary work: computational methods can facilitate manual analyses of qualitative researchers, while qualitative observations help quantitative researchers provide a window into learners' interactions. In the decades to come, computational methods can play a major role in creating synergy between qualitative and quantitative research. This paper makes a step toward bringing these two strands of research together through combining data visualization, Natural Language Processing, and Multimodal Learning Analytics.

8. ACKNOWLEDGEMENTS

We would like to thank the rest of the members of the Learning, Innovation, and Technology lab for their contributions to the initial study used in the development of this visualization.

ABSTRACT

Many universities are struggling with high dropout rates. It is important to recognize at-risk students as early as possible. In the event that only data of exam results is available, as much information as possible should be extracted from this data. Instead of just using the last state of a student's passed exams the entire student progress over several semesters could be used to build the predictive model. We propose a new time series representation of the study progress data and a new distance that we use in combination with an SVM kernel for the dropout prediction task. The proposed time series based approach achieves results similar to those of a non-time series based approach and can beat it starting from the fourth semester.

Keywords

student dropout prediction, time series distance

1. INTRODUCTION

Many universities are struggling with high dropout rates. According to the National Center for Educational Statistics, only about 60% of students who started their undergraduate studies in 2010 with a standard 4-year study program received a bachelor's degree from the same university within 6 years. In addition, around 80% of the students who started their studies in 2015 remained in the following year [5]. Especially in MINT study subjects, the dropout rate at the beginning of studies is particularly high. In [3], the authors report that the dropout rate of freshmen in the Electrical Engineering course is about 40%.

We have a data set of 857 computer science students from a German university who have been enrolled for at least one exam and who either have completed their studies with a bachelor's degree (421 students) or left their studies (at the university where they started) without graduation (436 students). Students who finished their studies in computer science without a bachelor's degree may also be subject chang-

ers, who have changed their main subject, or have continued their studies at another university or who have finally dropped out of their studies. We consider these 436 students as dropouts. When we speak of dropout prediction, we mean the prediction whether the students who have enrolled in computer science, for whatever reason, do not successfully complete the study at the same university. In Fig. 1 we show the distribution of the 436 dropouts in the first 10 semesters. Most dropouts are in the second semester (about 20%), so that by the end of the 2 semesters (i.e. the first year) about 25% of all dropouts have abandoned their studies. By the end of the 4th semester 50% of the dropouts have abandoned their studies and 80% by the end of the 10th.

Since most dropout students abandon their studies relatively early, it is important to recognize them as early as possible in order to start possible interventions. In [3] it is reported that human monitoring is used to solve this problem. A large number of students require considerable manual effort so automatic dropout prediction could facilitate the work.

Figure 1: distribution of dropouts

For reasons of data protection (GDPR) or other reasons, universities often have only limited amounts of data about their students. Since universities are legally required to store data like results of the exams, this data could be used to create dropout prediction models. If only data of exam results is available, as much information as possible should be extracted from this data. Instead of just using the last state of a student's passed exams the entire student progress over several semesters could be used to build the predictive models. The Sankey diagram in Fig. 2 visualizes the study progress of students that dropped out until the end of the 4th semester as well as graduates. Each node in a Sankey

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 500 - 503

Figure 2: Sankey diagram showing study progress of graduates and students who dropped out until the fourth semester. Legend: (11) Programming + Calculus I passed (10) Programming passed (01) Calculus I passed (00) Nothing passed

diagram is a combination of exams in a specific semester. For space reasons, the data in this illustration is only coded based on the two subjects Programming and Calculus I. In the caption of the visualization is a legend, which assigns the binary numbers to their corresponding combination of passing (1) and failing (0) exams. For example, the notation 110 represents those students that only passed Programming in the first semester. The visualization clearly shows that, based on the passed exam combinations, dropouts and graduates can have very different paths. This raises the core question of this study: How to create dropout prediction models based on previous exams, if not only the last state of passed exams is used, but also the students' entire study progress should be included? To do this, we will use the dynamic time warping distance and another proposed distance and show how the time series distances can be used in the kernel of an SVM for dropout prediction.

2. RELATED WORK

Many studies have been published on student dropout prediction using classifiers such as Support Vector Machine (SVM), Random Forest (RF), CART, C4.5, k-NN and Naive Bayes [1, 3, 4]. Since the data used varies widely and the data sets are often not published due to privacy concerns, it is often difficult to compare the results of different studies. A recent study [4] compares different strategies to numerically represent the student data. The authors divide the approaches of the representations for the student dropout prediction task into 3 areas: 1) Global Feature-Based (GFB) (features that can be heard from the student of the degree to which the student belongs); 2) Local Feature-Based (LFB) (Opting to use features that apply only to a particular degree results); and 3) Time Series (TS) (using the time information of the student's data to enrich the representation). The authors conclude that TS based approaches are less well suited. In this paper, we show how to improve a TS Distance-Based (TS-DB) approach presented in [1], so that this approach delivers better results.

3. METHOD

In this chapter, it is shown how a student study progress is transformed into a multivariate time series and how time series distances can be used to create SVM Kernel in order to create competitive dropout prediction models.

Let S be the set of all students with at least one exam at-

tempt. Let $C = \{c_1, \dots, c_n\}, n \geq 1$ be the set of exams that we want to use to create our student representation. We then define a mapping function $\psi_t^C : S \rightarrow \{0, 1\}^n$ that transforms the data of a student $s \in S$ to an n -dimensional binary vector and differ two notations $\psi_{t=k}^C$ and $\psi_{t \leq k}^C$.

The difference between $\psi_{t=k}^C$ and $\psi_{t \leq k}^C$ is that $\psi_{t=k}^C$ only shows the information describing which exams were passed in semester k and $\psi_{t \leq k}^C$ shows the information describing which exams were passed between first and k -th semester. Each value $\psi_t^C(s)[i] \in \{0, 1\}$ is representing the information whether an exam was passed or not as visualized in Fig. 3.

$$\psi_{t=k}^C(s) = \left[\underbrace{0 \text{ or } 1}_{c_1 \text{ passed in sem. } k} \quad \dots \quad \underbrace{0 \text{ or } 1}_{c_n \text{ passed in sem. } k} \right]$$

$$\psi_{t \leq k}^C(s) = \left[\underbrace{0 \text{ or } 1}_{c_1 \text{ passed until sem. } k} \quad \dots \quad \underbrace{0 \text{ or } 1}_{c_n \text{ passed until sem. } k} \right]$$

Figure 3: Visualization of a coded semester vector

Example: Having a set C of the three exams with $c_1 = \text{Calculus}$, $c_2 = \text{Linear Algebra}$ and $c_3 = \text{Programming}$ and a student s who passed Calculus in the first semester, Programming in the second and Linear Algebra in the third semester, the mappings of the two versions of ψ_t^C would be as visualized in Fig. 4

$$\begin{aligned} \psi_{t=1}^C(s) &= \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} & \psi_{t \leq 1}^C(s) &= \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} \\ \psi_{t=2}^C(s) &= \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} & \psi_{t \leq 2}^C(s) &= \begin{bmatrix} 1 & 0 & 1 \end{bmatrix} \\ \psi_{t=3}^C(s) &= \begin{bmatrix} 0 & 1 & 0 \end{bmatrix} & \psi_{t \leq 3}^C(s) &= \begin{bmatrix} 1 & 1 & 1 \end{bmatrix} \end{aligned}$$

$\underbrace{\quad\quad\quad}_{c_1 \quad c_2 \quad c_3}$ $\underbrace{\quad\quad\quad}_{c_1 \quad c_2 \quad c_3}$

Figure 4: Exemplary visualizations of $\psi_{t=k}^C$ and $\psi_{t \leq k}^C$

In the following, we will only use the alternative $\psi_{t \leq k}^C$ because it works better than $\psi_{t=k}^C$. $\psi_{t=k}^C$ was only introduced because it corresponds to the creation of the time series in [1] and so we can specify the exact difference in the modelling of the time series of the two approaches.

There are different ways to represent a student based on his previous examinations. A typical option would be to represent the student using the last state of his or her exam results $\psi_{t \leq k}^C$. Based on this, the distance between two students s_1 and s_2 could be calculated with $d(\psi_{t \leq 3}^C(s_1), \psi_{t \leq 3}^C(s_2))$. In this case, however, the information would disappear, as how the study progress of the students looked until then. As you can see in Fig. 2, student's study progress can be very different. Assuming that not only the final state of the exam results, but the complete study progress might have an impact on whether or not a student drops out in the future, we now define the multivariate time series for students:

DEFINITION 1. Let $C = \{c_1, \dots, c_n\}$ be a set of selected exams. Let $t_{ij} \in \{0, 1\}$ be the result of exam c_i until end of semester j of a student s . A student time series $T_k^C(s)$ representing the study progress of k semesters is defined by:

$$T_k^C(s) = [\psi_{t \leq 1}^C(s), \dots, \psi_{t \leq k}^C(s)] = \left[\begin{bmatrix} t_{11} \\ \vdots \\ t_{n1} \end{bmatrix}, \dots, \begin{bmatrix} t_{1k} \\ \vdots \\ t_{nk} \end{bmatrix} \right]$$

Thus, we can present a student as a temporal sequence of his completed semesters, each semester carrying different kinds of information. Let $T_k^C(s_1)$ and $T_k^C(s_2)$ be two multivariate sequences representing the current study progress of the two students s_1 and s_2 . To compare these two sequences, we need a similarity measure or a distance $d(T_k^C(s_1), T_k^C(s_2))$ for multivariate time series.

3.1 Time Series Distances

This subchapter shows the Dynamic Time Warping (DTW) distance and a new proposed distance for student time series.

3.1.1 Multidimensional Dynamic Time Warping

A well-researched distance for univariate time series is the DTW distance. In [6] the *multidimensional* DTW distance has been proposed and its application for the student dropout prediction in [1]. The following example shows the application of the presented model with DTW. Let s_1 and s_2 be two students, for whom the data of the first 4 semesters is available, and let $C = \{c_1, c_2, c_3, c_4\}$ be a set of 4 exams on which the two student time series (Fig. 5) are based:

$$\underbrace{\left[\begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \right]}_{= T_4^C(s_1)} \quad \underbrace{\left[\begin{bmatrix} 1 \\ 1 \\ 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \right]}_{= T_4^C(s_2)}$$

Figure 5: Two exemplary student time series

The example is chosen so that both students have the same status after the fourth semester with respect to exams C: $\psi_{t \leq 4}^C(s_1) = \psi_{t \leq 4}^C(s_2)$. The distance $d(\psi_{t \leq 4}^C(s_1), \psi_{t \leq 4}^C(s_2))$ for the vectors representing the last state would in this case be 0. However, if the entire course of study is included, then the distance would have to be greater than 0. In Figure 6 we show the calculation of the DTW distance $d(T_4^C(s_1), T_4^C(s_2))$ for these two students. By including the time series, the distance between the two students is no longer 0, although at

the end they have the same results with respect to C. To

(a) pairwise Manhattan distances of $T_4^C(s_1)$ and $T_4^C(s_2)$ (b) cumulative distances of $T_4^C(s_1)$ and $T_4^C(s_2)$

Figure 6: MD-DTW example for 2 students' time series

calculate the distance of the whole time series, a cumulative distance matrix (Fig. 6b) is calculated, based on the calculated distances of the pairs of the time units (Fig. 6a). The values at the index (i, j) of the cumulated matrix are calculated by a cost function γ , which is based on dynamic programming and is defined recursively in equation 1. The last calculated value $\gamma(4, 4) = 5$ indicates the DTW distance.

$$\gamma(i, j) = d(a_i, b_j) + \min \left\{ \begin{array}{l} \gamma(i-1, j), \\ \gamma(i-1, j-1), \\ \gamma(i, j-1) \end{array} \right\} \quad (1)$$

3.1.2 Weighted Semester Distance

Here we present another approach to the distance calculation of two time series with exam results. Unlike the DTW approach, only the results of the same semester are compared here. In addition, the influence of individual semesters is weighted differently. For two time series $T_k^C(s_1)$ and $T_k^C(s_2)$ we define the d_{WSD} distance:

$$d_{WSD}(T_k^C(s_1), T_k^C(s_2)) = \sum_{i=1}^k w_i d(\psi_{t \leq i}^C(s_1), \psi_{t \leq i}^C(s_2))$$

For k semesters, the weights w_i per semester are chosen as $w_i = \frac{i^2}{\sum_{j=1}^k j^2} = \frac{i^2}{\frac{1}{6}k(k+1)(2k+1)}$ so that $\sum_{i=1}^k w_i = 1$ and the later semesters are weighted more heavily than the first.

3.2 Time Series Kernel

A popular method for binary classification problems is the *support vector machine* (SVM). The decision rule formulation of the SVM (with L support vectors) using the kernel trick for an input vector x^* that needs to be classified is given by $f(x^*) = \text{signum} \left(\left[\sum_{i=1}^L \alpha_i y_i K(x^*, x_i) \right] - b \right)$. A well-known and often used kernel is the RBF-kernel and is defined by: $K_{RBF}(x, y) = \exp(-\gamma \|x - y\|^2)$. An adaptation of the RBF kernel to the Gaussian DTW (GDTW) [2] kernel based on the d_{DTW} distance is specified by:

$$K_{GDTW}(x, y) = \exp(-\gamma d_{DTW}(x, y))$$

Using the d_{WSD} distance we define the corresponding adaptation of the RBF kernel by:

$$K_{WSD}(x, y) = \exp(-\gamma d_{WSD}(x, y))$$

The parameter γ must be learned with the training data.

Table 1: Classification results (Recall, Precision, F_1) for student data including exam results up to the end of k -th semester

4. EVALUATION

The evaluation is done on a data set with 857 students. For each student, the following information about his or her achievements is available: idCourse, exam status (passed or failed) and the semester of the exam attempt. We evaluate how well the prediction works using the data available until the end of the 2nd, 3rd, 4th or 5th semester. The 1st is not considered since no advantages of time series can be used. For example, if the prediction for data including exam results until the end of the 4th semester is evaluated, all dropouts and graduates who have studied at least 4 semesters will be considered. It follows that with increasing semesters, there are fewer and fewer students that can be used for evaluation since students drop out or graduate before and cannot contribute to the training and evaluation.

The evaluation is performed 3 times with 10-fold stratified cross-validation. We use Recall (Re) and Precision (Pr) as evaluation measures. If as many dropout students as possible should be found, Recall should be as large as possible. If it is not very important that all are found, but the results should be really endangered students, then Precision should be as high as possible. In addition, the F_1 measure is specified, taking into account both Precision and Recall.

The length of the resulting numerical representation (multivariate time series vectors or simple vectors) depends strongly on the number of courses used since the vectors are created based on selected courses. In the data set, there are more than 100 courses. As you can see in Fig. 2, just a few exams are enough to show differences in the study progress of the dropouts and graduates. Therefore, we sort all courses according to the number of students who have enrolled in them and take $3k$ courses with the highest enrollment until k -th semester for the evaluation of students who studied at least k semesters (e.g., 6 courses with the highest enrollment until the 2nd semester for students who studied at least 2 semesters). The 3 courses are added per semester, as the curriculum includes about 3 courses per semester.

In Table 1, we compare the results of the two TS-DB approaches (numerical representation of a student is $T_k^C(s)$) based on the two SVM kernels k_{GDTW} and k_{WSD} . Additionally, two LFB approaches (numerical representation of a student is $\psi_{t \leq k}^C(s)$) with the RF and SVM (RBF kernel) classifiers are evaluated. If only the exam results until the end of the 2nd semester are used to create the prediction model, the LFB approach with the RF classifier achieves the best results in all three evaluation measures. The other approaches achieve similar or slightly worse results. In the 3rd semester, the TS-DB approach with the WSD kernel reaches the best Recall and F_1 value, whereby the LFB ap-

proach with the SVM classifier achieves a slightly better Precision value. However, from the 4th semester, the TS-DB approaches can take advantage and are better in all three measures. If the Recall or the F_1 measure is more important, then the proposed WSD kernel is more useful and if Precision is more important, the GDTW kernel is better.

5. CONCLUSION

Often only the data of the study progress per semester are available. Since these data are arranged chronologically, we have shown how the study progress data can be transformed into a multivariate time series. We presented a new kernel (WSD) and showed that the TS-DB based approaches deliver better results than LF based approaches (using only the final state of the exam results) from the 4th semester onwards. In future research, we will not only include the exam results (passed or failed) in the model but also other information such as the number of attempts or the grades.

ABSTRACT

A long line of literature has focused on the problem of selecting a team of individuals from a large pool of candidates, such that certain constraints are respected, and a given objective function is maximized. In this work, we extend the team formation literature by introducing the Guided Team-Partitioning (GTP) problem, which asks for the partitioning of a population into teams such that the centroid of each team is as close as possible to a given target vector. This formulation allows the team-builder to control the composition of the produced teams and has natural applications in practical settings. Algorithms for the GTP need to simultaneously consider the composition of multiple non-overlapping teams that compete for the same population of candidates. This makes the problem considerably more challenging than formulations that focus on the optimization of a single team. In fact, we prove that GTP is NP-hard to solve and even to approximate. The complexity of the problem motivates us to consider efficient algorithmic heuristics, which we evaluate via experiments on both real and synthetic datasets.

Keywords

Team Formation, Partitioning

The input of the general team formation problem consists of a pool of candidates, a set of constraints, and an objective function. The goal is then to strategically select a group of individuals from the pool, such that the group respects all the constraints and also optimizes the objective function. A long line of literature has addressed different versions of the problem that ask for the optimization of functions such as the quality of intra-team communication. Previous work has also considered a diverse array of constraints, such as those on the team's size, the team-builder's recruitment budget [7], the abilities of students [3, 4], the performance of the teams [2, 1], and the compatibility of the team members [5].

Sanaz Bahargam, Theodoros Lappas and Evimaria Terzi "The Guided Team-Partitioning Problem: Definition, Complexity, and Algorithm" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 504 - 507

In this paper, we extend the team formation literature by introducing an alternative formulation of the problem that asks for the partitioning of the given pool of candidates into *multiple* teams, while allowing the team builder to control the properties of each team. We refer to this paradigm as *Guided Team-Partitioning* (GTP). For instance, consider a teacher who is trying to partition the students in her class into groups, such that the distribution of talent and experience across the groups is balanced. We illustrate an example of this scenario in Figure 1. Conceptually, our goal is to

Figure 1: Standard Vs. Fair Clustering

avoid teams with an unfair advantage or disadvantage. We refer to (3, 3, 3) as the *target vector*, which is used to guide the partitioning task. We refer the interested readers to the long version of this paper for more examples [6].

1. PROBLEM DEFINITION

In this section, we begin by describing notational conventions that we will use throughout the paper; then we present the formal statement of the problems that we study. We start from a simple version of our problem with only one team. We show that even the simple version is NP-hard to solve and approximate. Then we move to partitioning problem with desired centroids. In Subsection 1.4, we describe our problem, GUIDED TEAM-PARTITIONING and we show that our problem is NP-hard to solve and approximate.

1.1 Preliminaries

We consider a pool \mathcal{R} of n individual experts. Each expert $\mathbf{r} \in \mathcal{R}$ is associated with a d -dimensional feature (skill) vector \mathbf{r}_i , such that $\mathbf{r}_i(f)$ returns the value of skill f for expert i . We also consider given a set of target vectors \mathbf{T} of k target points \mathbf{t} . The goal is to partition the pool of experts into k teams such that the cost of this partitioning is minimized. The cost for each team C_i , is the distance between the centroid of that team ($\text{mean}(C_i)$) to its target vector \mathbf{t}_i .

$$\text{Cost} = \sum_{i=1}^k \mathbf{D}(\text{mean}(C_i), \mathbf{t}_i) \quad (1)$$

We quantify the closeness between two vectors τ and t of dimension d , using the L_2^2 norm of their difference. We denote this by

$$\mathbf{D}(\tau, t) := L_2^2(\tau - t) = \sum_{i=1}^d (\tau(i) - t(i))^2$$

We define the **mean** of a set \mathcal{R} , consisting of n vectors $\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n$ as

$$\mathbf{mean}(\mathcal{R}) = \frac{\sum_{i=1}^n \mathbf{r}_i}{n}$$

1.2 The CIS Problem

In Characteristic-Item Selection (CIS) problem, the goal is to find a subset of a universe set, such that the mean of the subset is as close as possible to a designated point. This designated point represents the whole set. This intuition is captured in a formal definition as follows.

Problem 1 (CIS). *Given a set $\mathcal{R} = \{\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n\}$, a number ℓ , and a designated vector \mathbf{t} , find ℓ points (\mathcal{R}_ℓ) to remove from \mathcal{R} , such that **mean** of the remaining points $\mathcal{R} \setminus \mathcal{R}_\ell$ is close to target \mathbf{t} . More formally,*

$$\mathbf{D}(\mathbf{mean}(\mathcal{R} \setminus \mathcal{R}_\ell), \mathbf{t})$$

is minimized.

Lemma 1. *The CIS problem is NP-hard to solve and approximate.*

We refer the interested readers to the long version of this paper for proofs of the lemmas [6].

1.3 The CP Problem

Given a set of n workers with different skills and a set of k tasks that need to be done collaboratively with given average required skill levels for each task, the goal is to form teams of workers that their mean skill level matches each task the best. This team formation problem can be considered as one of the applications of the CP (Characteristic Partitioning) problem which is formally defined in the following problem

Problem 2 (CP). *Given a set $\mathcal{R} = \{\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n\}$ and target vectors $\mathbf{T} = \{\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_k\}$, partition \mathcal{R} into k partitions $\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_k$ such that*

$$\sum_{i=1}^k \mathbf{D}(\mathbf{mean}(\mathcal{C}_i), \mathbf{t}_i)$$

is minimized.

Corollary 1. *The CP problem is NP-hard to solve and NP-hard to approximate.*

1.4 The GUIDED TEAM-PARTITIONING Problem

For many applications, it is not necessary to assign *all* the points in the dataset to teams. For instance, when separating a workforce into teams so that each team has a specific level of expertise in each skill, it is acceptable to exclude some of the workers. In general, having the option to exclude up to a fixed number of points adds flexibility and can only make the problem easier to solve. We capture this intuition in a formal problem definition as follows.

Problem 3 (GUIDED TEAM-PARTITIONING). *Given a set $\mathcal{R} = \{\mathbf{r}_1, \mathbf{r}_2, \dots, \mathbf{r}_n\}$, and target vectors $\mathbf{T} = \{\mathbf{t}_1, \mathbf{t}_2, \dots, \mathbf{t}_k\}$, and a budget ℓ , find ℓ points (\mathcal{R}_ℓ) to remove from the dataset and partition the rest of the points $\mathcal{R} \setminus \mathcal{R}_\ell$ into k partitions $\mathcal{C}_1, \mathcal{C}_2, \dots, \mathcal{C}_k$ such that Cost =*

$$\sum_{i=1}^k \mathbf{D}(\mathbf{mean}(\mathcal{C}_i), \mathbf{t}_i)$$

is minimized.

Corollary 2. *The GUIDED TEAM-PARTITIONING problem is NP-hard to solve and NP-hard to approximate.*

This problem is clearly NP-hard, as it contains the CP problem as a special case (for $\ell = 0$).

So far we have discussed the GUIDED TEAM-PARTITIONING problem. For a collection of workers \mathcal{R} in which each worker has a proficiency level for each skill, the most natural translation of the target vectors is the mean of the proficiencies or the required skills of a given project. For instance, consider online labor markets such as Freelancer (www.freelancer.com), Guru (www.guru.com), and oDesk (www.odesk.com) where employers hire freelancers with specific skills to work on different types of projects. The required skills listed for each project in these platforms can be used as the target vectors. In such a setting, each team should poses a specific share of expertise across all skills that makes the team capable of finishing a particular task or project.

2. ALGORITHM

In this section, we describe GUIDEDSPLIT; it finds an efficient solution for GUIDED TEAM-PARTITIONING. We start by presenting algorithms to solve CIS and CP problem and then we use these algorithms to solve GUIDED TEAM-PARTITIONING problem.

2.1 Solving The CIS Problem

Although CIS problem is NP-hard to solve and approximate, we propose heuristic algorithms that work well in practice.

The CONVEXOPT Algorithm: We can formulate CIS problem as a Mixed Integer optimization problem to find a binary vector x such that $\mathbf{mean}(\mathcal{R}x) = \mathbf{t}$ subject to $\sum_{i=1}^n x_i = n - \ell$.

Since solving mixed integer problem is NP-hard and would require complex algorithms to solve, we instead relax this problem to a convex quadratic programming by removing the binary constraints as shown in Algorithm 1. This CONVEXOPT algorithm forms a nonnegative real-valued vector x such that $\mathbf{D}(\mathbf{t}, \mathbf{mean}(\mathcal{R}x))$ (Line 1) is small. Note that the aim is to find a subset \mathbf{S} of length $n - \ell$ such that $\mathbf{mean}(\mathbf{S})$ is close to \mathbf{t} , in another word ideally, we want $n - \ell$ elements of x to be equal $\frac{1}{(n-\ell)}$, and the rest be 0 (and $\mathcal{R}x = \mathbf{t}$). This constraint is implied in Line 4 and 3. The algorithm tries to find a vector x of real values such that its elements are between 0 and 1 and the sum of elements of x is at least $n - \ell$. Then we transform this real-valued vector to a binary vector by replacing the $n - \ell$ largest elements to 1 and the rest to 0. We used CVX package in Matlab to solve this convex quadratic programming.

Algorithm 1 The CONVEXOPT Algorithm

Input: Input set \mathcal{R} , target vector \mathbf{t} and number of points to be removed ℓ
Output: A subset \mathbf{S} such that $|\mathbf{S}| = n - \ell$

- 1: minimize $\mathbf{D}(\mathcal{R} * x * \frac{1}{n-\ell}, \mathbf{t}')$
- 2: subject to
- 3: $\text{sum}(x) \geq n - \ell$
- 4: $x \geq 0$ and $x \leq 1$ and $x \in \mathbb{R}$
- 5: Set $n - \ell$ largest values of x to 1 and the rest to 0
- 6: return $\mathbf{S} = \mathcal{R}(x)$

2.2 Solving CP Problem

Our algorithm for the CP problem, which we call the MAX BENEFIT algorithm, is a polynomial time algorithm that finds a partitioning of data points \mathcal{R} , into k partitions. The pseudocode of the MAX BENEFIT algorithm is shown in Algorithm 2.

Algorithm 2 The MAX BENEFIT Algorithm

Input: Input set \mathcal{R} , target vectors \mathbf{T} and number of partitions k
Output: Partitions \mathcal{C}

- 1: $\mathcal{C} = \{\}$
- 2: **for** \mathbf{r} in \mathcal{R} **do**
- 3: $j = \text{argmax}_{i=1 \dots k} (\mathbf{D}(\mathbf{t}_i, \text{mean}(\mathcal{C}_i)) - \mathbf{D}(\mathbf{t}_i, \text{mean}(\mathcal{C}_i \cup \{\mathbf{r}\})))$
- 4: Add \mathbf{r} to partition j , \mathcal{C}_j
- 5: **while** no convergence achieved **do**
- 6: **for** \mathbf{r} in \mathcal{R} **do**
- 7: $h =$ The partition \mathbf{r} belongs to
- 8: $\text{loss} = \mathbf{D}(\mathbf{t}_h, \text{mean}(\mathcal{C}_h \setminus \{\mathbf{r}\})) - \mathbf{D}(\mathbf{t}_h, \text{mean}(\mathcal{C}_h))$
- 9: $j = \text{argmax}_{i=1 \dots k} (\text{loss} + \mathbf{D}(\mathbf{t}_i, \text{mean}(\mathcal{C}_i)) - \mathbf{D}(\mathbf{t}_i, \text{mean}(\mathcal{C}_i \cup \{\mathbf{r}\})))$
- 10: Remove \mathbf{r} from partition h and update $\text{mean}(\mathcal{C}_h)$
- 11: Add \mathbf{r} to partition j and update $\text{mean}(\mathcal{C}_j)$
- 12: Return \mathcal{C}

2.3 Solving the GUIDED TEAM-PARTITIONING Problem

Let's assume we are given k partitions (such that mean of each partition \mathcal{C}_i is close to \mathbf{t}_i) and along with each partition, we are given q points (for all $q = 1 \dots \ell$) to be removed from that partition. Now we can develop a dynamic programming algorithm to optimally identify ℓ points to be removed from all partitions. Let $B(i, q)$ denote the benefit of removing the given q points from the i^{th} partition. The benefit is defined as how much the mean of a partition will get closer to its designated target. More formally the benefit of removing points \mathcal{R}_q from partition \mathcal{C}_i with target \mathbf{t}_i is $\mathbf{D}(\text{mean}(\mathcal{C}_i), \mathbf{t}_i) - \mathbf{D}(\text{mean}(\mathcal{C}_i \setminus \mathcal{R}_q), \mathbf{t}_i)$. Let also $MBR(i-1, j-q)$ denote the benefit of removing $j-q$ points from partitions 1^{st} to $(i-1)^{\text{th}}$ partitions. The final goal is to find the $MBR(k, \ell)$, the benefit of optimally removing ℓ points from first to last (k^{th}) partition. The following dynamic programming shows how we decide upon removing points from partitions optimally.

$$MBR(i, j) = \max_{0 \leq q \leq j} \{MBR(i-1, j-q) + B(i, q)\}$$

At this stage, we have the tool to remove ℓ points from all partitions. Now we can use Algorithm 2 to find the partitions \mathcal{C} and using Algorithm 1, we can find the q points to be removed from each partition. Putting everything together, we end up with Algorithm 3 which is an efficient solution to the GUIDED TEAM-PARTITIONING problem. We call this algorithm GUIDEDSPLIT.

3. EXPERIMENTS

Algorithm 3 The GUIDEDSPLIT Algorithm

Input: Input set \mathcal{R} , target vectors \mathbf{T} , number of partitions k and number of points to be removed ℓ
Output: Partitions \mathcal{C}

- 1: $\mathcal{C} =$ Partition \mathcal{R} into k parts using Algorithm 2
- 2: **for** \mathcal{C}_i in \mathcal{C} **do**
- 3: **for** $j = 1 \dots \ell$ **do**
- 4: $B(i, j) =$ Benefit of removing j points from partition p_i using Algorithm 1
- 5: **for** $i = 1 \dots k$ **do**
- 6: **for** $j = 1 \dots \ell$ **do**
- 7: $MBR(i, j) = \max_{0 \leq q \leq j} \{MBR(i-1, j-q) + B(i, q)\}$
- 8: return $MBR(k, \ell)$ and remove corresponding ℓ from partitions

In this section, we evaluate our algorithmic solution to the GUIDED TEAM-PARTITIONING problem. **Our datasets and implementation are immediately and freely available for download.**¹. We refer the interested readers to the long version of this paper description of the datasets and baseline algorithms, and detailed description of each experiment [6].

3.1 Experimental Evaluation

Having all the datasets and target vectors ready as the input of Problem 3, we compare the efficacy of GUIDEDSPLIT algorithm with the baseline algorithms. We implemented our algorithm in Matlab and used CVX package to solve the convex optimization problem in the CONVEXOPT algorithm. We compare the cost of our algorithm compare to all other baselines. This cost refers to the distance from the mean of each partition to its target vector, see equation 1. What follows is the detailed description of each experiment.

3.1.1 Effectiveness with respect to number of discarded points ℓ

The goal of this experiment is to demonstrate how different algorithms behave with respect to the number of removed points ℓ , as presented in the definition of Problem 3.

Figure 2 shows the cost (in log scale) versus ℓ . We observe that our GUIDEDSPLIT algorithm consistently outperforms the baseline algorithms for all target vectors, and the cost of GUIDEDSPLIT is significantly less than all the baselines. We also observe when all the targets are set to the mean, the RANDOM algorithm is doing well. This is simply because a random sample of the data is expected to have the same mean as the whole data.

An interesting observation is that when targets are equal to the mean of the dataset, Figure 2(a), as ℓ increases the cost of GUIDEDSPLIT increases as well. The reason is after finding partitions when $\ell = 0$, GUIDEDSPLIT finds near perfect solution in which mean of each partition is very close to its target. Removing points from the partition discomposes the obtained solution and makes the mean of partition far from its target. We also tried this experiment on other datasets; the results were similar, and GUIDEDSPLIT outperforms in those experiments as well. However, the algorithms were more competitive on Skills dataset. Thus due to lack of space, we only report results on Skills dataset.

3.1.2 Effectiveness with respect to number of partitions k

¹<https://github.com/sanazb/TeamPartitioning>

Figure 2: Different algorithms on **Skills** dataset with respect to increasing ℓ . The fixed parameters are $k = 5$, $n = 500$ and $d = 10$.

Figure 3: Different algorithms on **Skills** dataset with respect to increasing k . The fixed parameters are $n = 500$, $\ell = 50$ and $d = 10$.

Figure 4: Different algorithms on **Freelancer**, and **Guru** datasets.

The goal of this experiment is to demonstrate how the algorithms behave with respect to the number of partitions k . In these experiments, we show the cost (in log scale) versus different number of partitions ($k = 2, 4, 8, 16, 32$) and we fixed $n = 500$, $\ell = 50$ and $d = 10$ on **Skills** dataset and $n = 502$, $d = 4$ and $\ell = 50$ for **BIA** dataset. In the experiment on **BIA** dataset, to form fair teams of students with an equal level of expertise, the targets of partitions are set to be equal to the mean of the whole dataset. We present the results in Figure 3(a), Figure 3(b), and Figure 3(c) for all three different methods of choosing the target vectors (Random-Sobol, Mean, and Sampling methods) on **Skills** dataset and Figure 5 depicts the results on **BIA** dataset.

Figure 5: Different algorithms on **BIA** dataset with respect to increasing k . The fixed parameters are $n = 502$, $\ell = 50$, and $d = 4$.

3.1.3 Results on the Freelancer and Guru datasets

Guru and **Freelancer** datasets have a different dynamic compare to other datasets. In these datasets, we can use the required skills of the projects as the target vectors. Besides,

the projects posted in **freelancer** and **guru**, are the tasks that require a few skills and they can also be completed by a small team of experts. So we conducted an experiment specifically for these two datasets which indicates the performance of our algorithm with respect to the number of points n , the number of partitions k , and the number of points to remove ℓ .

For this experiment, we used the set of experts as input set \mathcal{R} , and the projects as target vectors \mathbf{T} . We tried $k = 2, 4, 8, 16, 32$, and for each value of k , we used k projects at random. We also set $n = k * 5$ and $\ell = k$ (and selected $n + \ell$ experts as random as the input \mathcal{R}). The intuition behind is due to the inherent nature of projects posted in **Guru** and **Freelancer**; these projects are small projects that usually do not need more than 5 people to be completed. By setting $n = k * 5$ and $\ell = k$, ideally, the size of each team would be 4. The results in Figure 4(a) and 4(b) illustrate **GUIDEDSPLIT** algorithm outperforms baseline algorithms on **Freelancer** and **Guru** datasets, and find teams of experts whose proficiencies are close to required skills of projects.

ABSTRACT

There is a long history of research on the development of models to detect and study student behavior and affect. Developing computer-based models has allowed the study of learning constructs at fine levels of granularity and over long periods of time. For many years, these models were developed using features based on previous educational research from the raw log data. More recently, however, the application of deep learning models has often skipped this feature-engineering step by allowing the algorithm to learn features from the fine-grained raw log data. As many of these deep learning models have led to promising results, researchers have asked which situations may lead to machine-learned features performing better than expert-generated features. This work addresses this question by comparing the use of machine-learned and expert-engineered features for three previously-developed models of student affect, off-task behavior, and gaming the system. In addition, we propose a third feature-engineering method that combines expert features with machine learning to explore the strengths and weaknesses of these approaches to build detectors of student affect and unproductive behaviors.

Keywords

feature engineering, student affect, disengaged behavior, deep learning

1. INTRODUCTION

The educational data mining community has developed numerous models to detect unproductive student behaviors and affective states and study how these measures correlate with short- and long-term learning outcomes. Estimates produced by detectors of student affective states and unproductive behavior, for example, have been found to predict student standardized test scores [15], whether a student chooses to attend college [16], and whether they pursue a degree in STEM [17], and even later pursue a STEM career

[11], from estimates produced from interaction logs collected as they worked on mathematics problems in seventh grade. The predictive power of these detectors along with a general desire to understand and improve the student learning process has led to a significant amount of research around developing these models.

The primary goal of this paper is to compare the two methods of generating features to predict student affect and unproductive behaviors. It is also important to consider whether some models perform better for certain types of features. Conversely, other simpler models such as a decision tree or logistic regression require feature engineering or aggregation in order to incorporate labeled and unlabeled data. Additionally, these models would be unable to easily observe unlabeled data in a semi-supervised learning manner [19].

In this work we re-develop detectors of student affective state [5], off-task behavior [15], and gaming the system [13], comparing new models to previously-developed models, to address the following research questions: 1) Which leads to better model performance (AUC ROC and Kappa), expert-engineered features or machine-learned features, for detectors of affect and unproductive behaviors? 2) Does combining expert-engineered features and machine learning-based feature generation improve model performance for detectors of affect and unproductive behaviors? 3) Does incorporating unlabeled data improve model performance for detectors of affect and unproductive behaviors?

The development of affect detectors within ASSISTments has improved in recent years. Initial work has explored the use of expert-engineered features to develop and evaluate detectors through a population validity study [12]. Recently, a deep learning approach was applied [5], utilizing the engineered features within a recurrent neural network to predict the four labels of affective state simultaneously over time.

This work utilizes two datasets¹ consisting of student interaction log data collected within the ASSISTments computer-based learning platform. The content within the system consists primarily of mathematics problems for students in grades 6-8. Students working in the system receive immediate correctness feedback on each problem with the ability to make multiple attempts, and have the ability to ask for on-

demand computer-provided aid in the form of hints or scaffolded problems. These interactions and timing information are the data used to construct most of the expert-engineered features utilized in this work. The ground-truth labels of both student affect and off-task behavior were collected using quantitative field observations following the Baker Rodrigo Ocumpaugh Monitoring Protocol (BROMP) [1].

We analyze gaming the system using a data set collected via text replays [2]. The ground-truth labels of student gaming were collected using post-hoc examinations of sequences of student data following a set of criteria outlined in [2].

2. METHODOLOGY

Jiang et al. [10] compared two feature engineering methods, expert-generated and deep learning-based, for the development of affect and off-task behavior detectors within the Betty's Brain learning system. This work will test the generalizability of their findings, explore the strengths and weaknesses of each method, and explore the incorporation of unlabeled data during model training.

Each of the models described next were trained and evaluated using stratified 10-fold student-level cross validation. We stratified each fold based on the number of occurrences of positive labels of each outcome label at the student level to generate the folds of the cross validation.

2.1 Utilizing Expert-Engineered Features

The first set of models use expert-engineered features to detect each label of student affect, off-task behavior, and gaming the system using methods similar to those implemented in previous works. The expert features are first generated using the raw action-level log data; 92 features are created for the affect and off-task data while 33 are generated for the gaming detectors in alignment with the features used in previous works. The features are generated to describe the actions that occur in 20 seconds of observation but also include neighboring actions that go beyond those 20 seconds to capture the full context. We apply a Naive Bayes classifier, a REP tree classifier and a Long-Short Term Memory (LSTM) deep learning network [9] for the gaming, off-task behavior, and affect detection tasks as these were found to work well in previous works [13][15][5].

2.2 Deep Learning Models

Unlike the expert-engineered features, the machine learned feature set uses the raw action logs of each student, ignoring the clips and clip-level features described in the previous section. For this feature set, a LSTM model is applied over the raw data to predict each outcome using a set of uninterpretable features learned within the hidden layer of the network. One potential drawback of using a LSTM model in this way is that it assumes that each timestep in the given sequence occurs at regular intervals which, of course, is not the case. Therefore, to reduce the variance of this interval, a similar practice as was applied to the affect detector model using expert-engineered features. This allows the model to divide sequences of student actions where long intervals may occur between subsequent actions; where the amount of time between two subsequent actions of the same student is greater than 5 minutes, the sequence is divided into two smaller sequences to be input into the model.

Each model utilized the same raw action-level log data that was used to generate the expert-engineered features described in the previous section. In addition to the interaction descriptors such as response correctness and whether the student requested a hint, the knowledge component associated with each problem was also included as a large 1-hot encoded vector in an effort to supply these LSTM models with the same information with which the expert-generated features had access. In addition to these described action logs, the set of features supplied to the gaming model included an additional field corresponding to the computed Levenshtein distance of each students sequence of incorrect responses (where such sequences of incorrect responses existed) within each problem as was computed for the expert-engineered features of this detector. We incorporated this feature to provide consistency in the information that is exposed to both the machine learning model and the expert feature-engineering process, although we acknowledge that the feature itself is a transformation of the raw responses (i.e. can be described as an expert feature) and was only found to be predictive of gaming the system through prior work exploring the development of expert features for this task [14].

Each of the three LSTM models created for each label of student affect, off-task behavior, and gaming the system followed the same general structure comprised of an input layer feeding into a fully-connected recurrent hidden layer of 200 LSTM nodes, and then feeding into an output layer of either 2 nodes (corresponding to a 1-hot encoded positive and negative indicator of either off-task behavior or gaming the system) or 4 nodes (corresponding to a 1-hot encoded vector with one value per observed affective state). The purpose of the hidden layer is to learn a set of 200 features from the raw action logs that are predictive of each outcome label. The commonly applied technique of dropout [18] is applied between the hidden and output layers of the network in an attempt to reduce overfitting. In all cases, a softmax activation function is applied to the output of each model and trained using multiclass cross entropy.

2.3 Machine-Learned Expert-Inspired Features

The third feature set proposed for comparison combines aspects of both expert-engineered features and machine learning. Expert features may be able to help guide a machine learning model to learn better sets of features than either method individually. In addition, since each set of expert features were presumably developed with a particular set of outcome measures in mind, such labels may also be able to help guide a machine learning model to produce meaningful, albeit uninterpretable, sets of features to detect such behaviors and affective states.

Specifically, this method utilizes a 2-step training process for a machine learning model. First, an LSTM model is built to use the raw action-level logs as input (just as was done in the previous section for the models utilizing machine learned features), but in addition to predicting each label, the model is trained to predict the set of expert-engineered features as a multi-task learning problem [7]. As the affect and off-task behavior detectors utilize the same set of action logs and expert-engineered features, we build one model to read the interaction logs. This model will predict each of the set of

Table 1: Comparison of feature sets across each of the detector models with and without co-training.

Outcome	Feature Set	Model	AUC	Kappa	Co-Trained* AUC	Co-Trained* Kappa

*All co-training used an LSTM model. Models using the machine learned features all used co-training.

expert-engineered features corresponding with the given set of actions, the affective state label, and the off-task behavior label simultaneously. Similarly, for the gaming detector, the raw actions are supplied as input to a LSTM model that predicts both the set of expert-engineered features and the gaming labels. In this way, the hidden layer of the respective models is regularized to learn a set of features that is both able to construct the set of expert features (although likely with some error) as well as predict the outcome labels for which the features are intended.

Once these LSTM models are trained, the hidden layer is extracted and used as the third and final set of features compared in this work. This feature set, referred to as “machine-learned expert-inspired” features, is then supplied as input to each of the respective models used in previous work.

2.4 Exploring the use of Co-Training

In this work, we use the term “co-training” to describe the use of both labeled and unlabeled data to inform model estimates and the methods differ from that of other works describing co-trained models [3]. Given the nature of the observation-based label collection procedure, not all examples in our data (whether considering actions or clips) has an associated affect or behavior label. While there are several modeling methods that exist to incorporate this unlabeled data into each model, the already-described LSTM model inherently allows for this co-training to occur given its sequential structure. The model uses the current supplied timestep along with a learned-aggregation of previous time steps in order to better inform each prediction.

3. RESULTS AND DISCUSSION

We compare the results of each set of models within each of the three outcome measures of affect, off-task behavior,

and gaming behavior using the metrics of AUC ROC and Cohen’s Kappa. In the case of affect, AUC ROC is calculated using a multi-class variant of the metric [8], while Kappa is calculated as multi-class Cohen’s Kappa, while the models of off-task behavior and gaming use an optimized form of Kappa by learning an optimal decision (0,1) threshold using the training set of each respective fold within the cross validation. Higher values of either metric are indicative of higher model performance with AUC values at 0.5 and Kappa values at 0 indicating chance performance.

The results of each model is reported in Table 1. Compared to the models utilizing machine learned features, the expert-engineered features lead to notably higher performance across all the outcome labels in regard to both AUC and Kappa. When comparing the performance of the models using the machine-learned expert features (our proposed third feature set), the difference in performance is not as dramatic, but leans in favor of the expert-engineered features leading to superior models. By contrast, the machine learned expert features led to models that outperform those using expert-engineered features in regard to off-task behavior in terms of both AUC and kappa and is equal in regard to detecting gaming in terms of AUC, but appears to perform less well in detecting student affect.

Despite the small number of cases where the models trained from expert-engineered features did not outperform the others in either AUC or Kappa, these models exhibited consistently high performance in both metrics across all outcomes. It can further be concluded that co-training led to higher AUC than the non-co-trained variant of each detector. This, however, was not always the case in regard to Kappa, where the co-trained models of gaming and affect using expert-engineered features exhibited notably lower values.

4. FUTURE WORK

Among the detectors, it was found in some cases that there was disagreement between the metrics used; the co-trained model of affect exhibited higher AUC than the non-co-trained model, but a lower value of Kappa. Previous work has explored this case across several commonly-applied metrics [4], but further work is needed to further explore and leverage modeling techniques to produce detectors that exhibit high performance across all these metrics.

The use of the highest-performing models across each of these detectors can also be used in future research to study other aspects of student learning. This extends beyond the already-discussed application in predicting student longer-term outcomes, and includes the study of other aspects such as the dynamics and chronometry, studied using affect detectors in prior work [6].

5. CONCLUSIONS

This work investigates whether expert-engineered features lead to higher performing detectors of student affect and disengaged behavior as compared to using automatically-distilled features learned through a machine-learning approach. We found that the use of expert features led to the most consistently high-performing models. Using co-training led to even better models in most cases.

The use of expert-engineering to develop features, while perhaps more difficult in regard to time, effort, and likely cost, does appear to lead to greater benefits than simply applying a machine learning model to automatically distill features from the raw data, based on the results found in this work.

ABSTRACT

This paper explores in depth the suitability of the 2012 Automated Student Assessment Prize (ASAP) contest's essay datasets. It evaluates the potential of deep learning and state-of-the-art NLP tools in automated essay scoring (AES) to predict not only holistic scores but also the finer-grained rubric scores, an area underexplored but essential to provision formative feedback and uncover the AI reasoning behind AES. For comparison purpose, this paper advocates the need for transparency when sharing AES processes and outcomes. Finally, it reveals the insufficiency of ASAP essay datasets to train generalizable AES models by examining the distributions of holistic and rubric scores. Findings show that the strength of agreement between human and machine graders on holistic scores does not translate into similar strength on rubric scores and that the learning made by the machine barely exceeds the performance of a naïve predictor.

Keywords

Automated Essay Scoring; Automated Student Assessment Prize; Deep Learning; Natural Language Processing; Rubrics

1. INTRODUCTION

With the soaring development of deep learning and NLP, the interest in pushing further the limits of AES and harnessing the potential of valuable hand-graded essay datasets has been reinvigorated. This effervescence, however, is accompanied by a lack of transparency, although involuntary, that sometimes even prevent to measure and compare progress made in AES, prompting for some protocol on how to report research processes and outcomes in this area. This paper assesses the value of one of the most used set of datasets to train AES models, the free Automated Student Assessment Prize datasets, and sheds light on the factors that alter proper comparison between researchers' models. It investigates the capacity of deep learning in pair with the extensive range of writing features available nowadays from cutting-edge NLP tools to predict both holistic and rubric scores, a research orientation barely explored at this time and key for the provision of finer-grained formative feedback to student writers.

2. METHODOLOGY

The Automated Student Assessment Prize (ASAP) contest was launched in 2012 to evaluate the progress in AES and its readiness to be implemented across the United States in state-wide

writing assessments [4]. The Hewlett-Packard Foundation funded the Automated Student Assessment Prize contest that was hosted on the Kaggle platform to invite as many participants from the community of data scientists. Eight essay datasets were collected from these state-wide assessments and were graded following a thorough scoring process by subcontracted commercial vendors. These state-wide assessments were written by Grade 7-10 students from six different states. Each essay dataset originated from a single state-wide assessment targeting a specific grade (7-10) and state. The ASAP contest required participants to develop a model that would automatically score all these datasets and measure the level of agreement between their developed machine grader and the resolved human scores using the quadratic weighted kappa (QWK) metric. Both commercial vendors and data scientists from academia participated in the contest, and winners were determined based on the average QWK on all eight essay datasets. Although necessary for contest purposes, this proves not to be an effective way to transparently compare and report research processes and results given that each essay dataset has a unique setting, such as the type of writing construct (persuasive, source-based, expository, narrative), which at its turn requires a customized approach. Following the publication of the contest outcomes [4], warnings [4] came against concluding that AES was actually beating human graders just because it merely surpassed the level of agreement among human graders. For example, it was showcased [4] that AES systems could be fooled by only submitting text with the proper number of words, demonstrating "how smart" AES really was. Obviously, the ASAP study design had some limitations including the fact that none of the essay datasets had an articulated writing construct, most essays were too short and had on average between 94 and 381 words, suffered from a bias in the way holistic scores were resolved, had small scoring scales, and most of them did not have any scoring rubric [4]. The essay dataset #8 (Grade 10, narrative, mean number of words of 622) was the only exception to this and could at least test the writing ability of students. This makes the eighth dataset promising for machine to learn and provision formative feedback to both students and teachers. However, the main shortcoming of the eighth dataset is its small sample size, that is, only 722 of the original essay samples have been made available to the public.

This paper continues and extends the work undertaken by [1] in which the potential of deep learning in AES is evaluated. Because the essay sample size is very small, the latest advances in NLP along with a deep neural network (at least three hidden layers) were adopted to facilitate the detection of writing patterns instead of working directly with the raw text of student writings through a sequence model (i.e., a long short-term memory recurrent neural network). Hence, each of the 722 essays was processed by the Suite of Automatic Linguistic Analysis Tools¹ (SALAT). Among others, SALAT provides a set of baseline metrics related to word

David Boulanger and Vivekanandan Kumar "Shedding Light on the Automated Essay Scoring Process" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 512 - 515

¹ <https://www.linguisticanalysistools.org/>

frequency, text content, and lexical sophistication. The generic lexical sophistication metrics include among others psycholinguistic word information metrics (e.g., concreteness and familiarity), lexical frequency and range metrics (words occurring in a wider range of texts) based on large English corpora, and syntactic categories (e.g., number of adjectives and nouns). It also measures over 400 indices of lexical sophistication related to word and n-gram frequency and range, academic language, n-gram strength of association, contextual distinctiveness, word recognition norms, semantic network, and word neighbors. Several of these metrics are normed according to the number of word or n-gram occurrences found in large corpora of English writings and frequency lists. Moreover, SALAT supplies 367 indices evaluating the syntactic sophistication and complexity of English writing, grouped into four categories: 14 syntactic complexity analysis indices, 31 indices on clausal complexity, 132 indices related to phrasal complexity, and 190 syntactic sophistication indices. Finally, SALAT comes up with a set of over 150 features related to local, global, and overall text cohesion. Texts are first lemmatized and grouped per sentence and paragraph before computing any cohesion metric. It also employs a part-of-speech tagger and synonym sets from the WordNet lexical database for the computation of these cohesion metrics, which are grouped among five categories: connectives, givenness, type token ratio, lexical overlap, and semantic overlap.

Hence, a vector of 1,463 writing features was generated for each essay sample. Because of this huge number of features, [1] computed the correlation coefficients using the non-parametric Spearman correlation between every writing metric and holistic scores. The writing metrics were then sorted by the strength of association from strongest to weakest. Several subsets of writing metrics containing the most correlated metrics were created, that is, vectors with 192, 128, 96, and 64 writing features by essay sample were input into a deep neural network. The best results were delivered through the 96-feature dataset², which is re-used in this study for rubric score prediction and for comparison with [1].

ASAP eighth essay dataset encloses holistic scores resolved by adjudication rules applied on the rubric scores of two human graders. Each human grader is asked to score the essay as per six rubrics and to assign a discrete number between 1 and 6 to each rubric. However, holistic scores are derived from only four rubric scores (1, 2, 5, and 6) according to the following formula: $R1 + R2 + R5 + 2 \cdot R6$. Each rubric score is the sum of the two human ratings except for cases in which the human ratings do not consistently agree with each other. In such cases, a third human rater scores the essay, assigning 1-6 scores to each rubric. The rubric scores are then calculated by multiplying the third human rater's ratings by two. This involves that all rubric scores range from 2 to 12. However, ASAP only provides individual human ratings (1-6). Hence, this research work compiled those resolved rubric scores as described above.

3. ANALYSIS & RESULTS

The purpose of this study is to investigate the feasibility and the benefits of applying automated essay scoring at the rubric level. Rubric scores are a form of high-level formative feedback that can be provided both to student writers and teachers. Moreover, as depicted in Figure 1 [1], accurately predicting essays' holistic scores on a wide scale (i.e., 10-60) when trained with a rather

small sample dataset and an unbalanced score distribution proves a daunting task that goes far beyond computing a good "kappa" value, as publications subsequent to the ASAP contest continued to report. 530 (73.4%) essay scores out of 722 range between 30 and 40 (40-60%), while 707 (97.9%) essay scores lie between 25 and 50 (30-80%), leaving to the machine only three essays from which to learn high-quality writing (> 80%).

Figure 1. Distribution of holistic scores.

This paper hypothesizes that holistic scores would be better predicted through the prediction of its constituent rubric scores. For instance, if the distribution of holistic scores was uniform, there would be about $722/51=14$ examples per holistic score, not much to learn all the intricacies of English writing. On the other side, the scale of rubric scores ranges from 2 to 12, implying that in the best case there would be 66 essays per rubric score, more essays from which to assess a narrower writing competence. Figure 2 exhibits the distribution of scores of each rubric.

Figure 2. Distributions of rubric scores.

Table 1 delineates the agreement levels among rubrics and shows that they generally strongly agree with each other. It can also be noticed from Figure 2 that the most frequent score within each rubric is "8," suggesting that an AES system could naively predict scores of "8" for all rubrics and a holistic score of 40. The performance of such a naïve AES system (aka majority classifier) is measured by three metrics and reported in Table 2: the QWK, the percentage of exact predictions, and the percentage of adjacent predictions (off by 1). The QWK measures the level of agreement between two raters by controlling for random guessing and by penalizing exponentially (quadratic) higher distances between pairs of ratings.

Both supervised classification and regression techniques have been leveraged to model rubric scores. Table 3 reports the performance of six distinct deep learning architectures trained,

Table 1. Level of agreement among rubrics (QWK)

	R1	R2	R5	R6	Avg.
Rubric 1	-	0.88	0.79	0.68	0.78
Rubric 2	0.88	-	0.80	0.71	0.80
Rubric 5	0.79	0.80	-	0.79	0.79
Rubric 6	0.68	0.71	0.79	-	0.73

Avg.=Average of all rubrics combined; HS=Holistic scores

validated, and tested on the ASAP eighth dataset and its derived 96-feature dataset [1]. The 722 essays have been randomly split into a training set (85% = 614 essays) and testing set (15% = 108 essays). Although validation results are not reported here, 5-fold cross-validation was performed for each architecture, implying that the training set was randomly split into a smaller training set (80% = 491 essays) and a validation set (20% = 123 essays). Furthermore, this study unsuccessfully attempted to replicate the results reported by [1], that is, a QWK of 0.80 by running 10 times the available code. The obtained QWK values ranged between 0.51 and 0.74 with a mean of 0.63, suggesting that the results reported by [1] were subject to sampling error. Because this shuffling of essays among the training, validation, and testing sets combined with an unbalanced distribution of essay scores highly influence the machine learning and the resulting predictions, this study reports performance on the training and testing sets as the average of five replications [2] (different samplings) instead of picking up the “highest kappa” generated to avoid overfitting the AES models to the testing set.

The first architecture is a classifier selecting the most likely rubric score among a set of 11 discrete scores between 2 and 12. The second architecture is identical except that it leverages in addition a bagging ensemble technique. In other words, each model trained per fold during cross-validation makes up a machine grader, giving five machine graders, each with its own “expertise,” that determine the final rubric score by averaging their predicted score. The third architecture is a regressor that computes a single real-number score (e.g., 7.4398) and rounds it to the nearest integer, truncating it to 2 or 12 if the real number falls short or exceeds the scale. The fourth architecture is a regression ensemble (bagging). The fifth architecture is a regressor that considers the interdependencies among rubrics, from which holistic scores are derived. Thus, instead of predicting a single rubric score, this approach predicts all four rubric scores at once. Then the agreement level between the machine and the human graders for each rubric is analyzed and reported independently. Finally, the sixth architecture employs a bagging ensemble technique on top of the fifth architecture to predict rubric scores. Table 4 delineates the final hyperparameters of the various architectures.

4. DISCUSSION & CONCLUSION

Figure 2 shows that the most frequent score is “8” for all rubrics and that all rubrics have similar distributions except for Rubric 6. In addition, Table 1 shows that the rubric scores are highly dependent on each other, that is, they exhibit consistent agreement among them. The QWK values all range from 0.68 to 0.88. In particular, Rubric 6 has a slightly lower average agreement level with other rubrics (QWK=0.73) than the other rubrics (R1=0.78, R2=0.80, R5=0.79), which may account for its slightly different distribution. In practical terms, Rubric 6 being about grammatical and spelling conventions, this may relate to the intuition that the content and ideas, organization, or the sentence fluency of a text do not entirely depend on the mechanics of the student’s writing.

Table 2 reveals that 40.0%, 43.1%, 43.8%, and 34.3% of the rubric scores have been given an “8” by the human graders. This implies that systematically assigning an “8” to all rubrics would “predict” on average exact and adjacent scores 40.3% and 69.6% of the times. An awesome performance for a completely naïve AES model! Interestingly, the QWK metric proves to be an effective indicator to detect random guessing as shown by the 0’s in every rubric. It is, therefore, imperative that trustable AES models reach exact and adjacent match percentages significantly higher than those of this majority classifier.

By aggregating and selecting the best performance per rubric on the testing set, all architectures combined as demonstrated at the bottom of Table 3, it can be observed that on average the QWK’s lie between 0.48 and 0.55, much lower than the 0.80 QWK reported in [1] and the average 0.63 QWK replicated in this study

from [1]’s code, meaning that a high agreement level between human and machine graders on holistic scores does not necessarily translate into an as high level of agreement on rubric scores. This may be surprising given the much smaller scale of rubric scores. Moreover, deep learning’s best exact match percentages range between 44.4% and 51.0%, only 4-11% higher than the majority classifier (40.3%). As for adjacent match percentages, on average rubric scores fall between 86.8-89.5% of the times around +/-1 the actual rubric scores compared to 69.6% for the majority classifier. In other words, approximately 39% of rubric scores are off by 1 and 12% are off by 2 or more.

Research works having dealt with models predicting rubric scores trained on the ASAP datasets are quite rare. Among the very few is a feature-engineered AES system called SAGE [5], which was designed and tested using several machine learning techniques: linear regression, regression trees, neural network, random forest, and extremely randomized trees. The literature shows that SAGE appears to be currently the most powerful AES system in terms of agreement level (QWK=0.805) on ASAP eighth dataset. SAGE is unique in that it calculated for the first time 29 novel semantic coherence and 3 novel consistency metrics in addition to 72 more traditional linguistic and content metrics. Because these novel metrics were directly related to the second rubric (Organization), the authors also trained a model to predict the score of that rubric and reported a QWK of 0.70. However, it is not specified whether the agreement level was assessed using the 1-6 human rubric scores or the 2-12 resolved rubric scores. Interestingly, SAGE was tested using all the 1,527 [4] original essay samples available during the ASAP contest. Since only a subset (722) is now available since the contest is over, most research works have reported their performance on that subset, thus jeopardizing the fair comparison of those AES models against SAGE. Similarly, another AES system was implemented using a Common N-Gram classifier [3]. Each essay was represented by a set of n-grams, made up of either the actual words, stemmed words, or characters. The AES system trained two machine graders, both of which predicted rubric scores on the 1-6 scale. Table 5 reports the best agreement levels per rubric between the machine and human graders and between the two human graders as reported by [3].

Table 5’s results provide further evidence that high levels of agreement between machine and human graders on the ASAP eighth dataset’s holistic scores do not translate into similarly high agreement levels on the rubric scores, which again questions the humanlike “expertise” of AES systems [4]. This also leads to

conclude that the ASAP eighth dataset, the best that the ASAP contest delivered in terms of realistic essays, is clearly insufficient to train effective AES models. To counter tentatively the imbalance in the distribution of holistic scores, this study retrained the six models described earlier and assigned weights to the essay samples based on the frequency of essays per holistic score as shown in Figure 1. Yet, the performances were inferior to those reported in Table 3 and, hence, not reported.

Table 5. Best QWK results per rubric

	Rubric 1	Rubric 2	Rubric 5	Rubric 6
H1	0.482	0.455	0.489	0.454
H2	0.394	0.377	0.459	0.436
H1H2	0.523	0.533	0.498	0.532

H1=1st human grader; H2=2nd human grader; H1H2=Agreement between both graders

Finally, this paper analyzed the accuracy of the fifth and sixth models in predicting holistic scores out of the four predicted rubric scores to better explain how they are derived. The two models at best yielded on average a QWK of 0.56 and exact and adjacent match percentages of 12.5% and 26.8. This performance is equivalent or worse than the majority classifier. AES at the rubric level seems more challenging than it first appears.

For comparison purpose, this study was constrained to only analyzing the dataset of the 96 most correlated metrics with holistic scores as used by [1]. However, next steps should include identifying the writing indices that really contribute to each rubric score and assessing the size of their contribution. This would imply training each rubric model many times, each time randomly selecting a new set of writing indices (e.g., 50) and analyzing how the rubric model’s performance and the weights of its neural network’s very first layers vary as the set of writing features change. Moreover, a hybrid feature-based and end-to-end deep learning architecture should be explored, combining both writing features from NLP tools and the raw texts input into a sequence model with an attention mechanism. This would produce very fine-grained feedback by not only providing rubric scores but also highlighting portions of an essay that contributed to the predicted holistic and rubric scores and reporting the suboptimal writing indices affecting these text passages, hinting student writers about the importance and ways to improve their writing.

ABSTRACT

Determining how to select items for practice is an important task for any adaptive training system. Prior work has tried to create systems for second language learners (L2) to learn Mandarin tones, but such work does not often have a well-determined algorithm to choose items for practice. In order to develop a model for adaptive practice selection, we designed an experiment and asked L2 learners on Amazon Turk to finish a series of tone learning trials. Using this data we ranked the difficulty level of the stimuli and incorporated a quadratic function of difficulty for prior successes and failures into the Performance Factors Analysis (PFA) model. Results of logistic regression were used to compute the optimal difficulty level for each tone. For the four Mandarin tones, the optimal difficulty scores were 0.86, 0.75, 0.54 and 0.60, respectively. Crossvalidated results showed that the new PFA-Difficulty model had better performance than the original PFA model. While the advantage was not large, the new model allows for clear inferences about optimal item difficulty that can be used by an adaptive training system to select items for practice.

Keywords

Mandarin tone, Difficulty level, Performance factors analysis, Adaptive training.

1. INTRODUCTION

In Mandarin, there are four lexical tones: Tone 1, a high-level tone; Tone 2, rising tone; Tone 3, a low falling or low falling-rising tone, and Tone 4, a falling tone. It is a challenging task for second language learners (L2) to distinguish four tones [1,2]. Adaptive training system is thought to be an effective tool to train learners to acquire new skills by selecting items and adjusting presentation orders to address learner variability.

However, only a few studies have tried adaptive training systems for tone learning. Shih et al. [1] roughly selected items based on the talker-to-listener distance to control the task difficulty as they thought that the speech projected over a greater distance is easier while nearer is more difficult. Feiya Li et al. [2] used a hybrid training system which combined adaptive training with high variability phonetic training to train Japanese learners on Mandarin

tones. However, they did not provide details of how they selected the items or developed the system.

How to select materials according to learners' capability is a crucial issue. The overall goal of this study was to develop a model for adaptive practice selection for Mandarin tone learning. While prior work by Pavlik and Anderson has computed optimal practice levels [3], this work relied upon a model of spaced practice to justify the inverted U-shaped optimal difficult curve that was derived. This seems infeasible in the domain of tone learning since spacing will always be rather narrow on average with only 4 tones. Another option is to select items based on their difficulty level. Research has shown that adapting the difficulty of training based on learners' performance can improve the efficiency of training [4]. Similarly, Kelley [5] suggested that keeping an appropriate level of difficulty can make training effective. If a task is too easy, learners may learn very little probably because low levels of mental effort don't cause as much learning. While if the task is too difficult, learners may be unable to encode the experience and show weaker learning. Thus, the relationship between difficulty and learning is likely similar to the Yerkes-Dodson law (often expressed as an inverted-U function) which suggests that there is an optimal level of arousal for an optimal performance, over or under arousal reduces task performance [6]. We hypothesized that students would benefit more from example practice in a medium range of difficulty when learning tones, the relationship between difficulty and learning is also in an inverted-U shape.

Performance Factors Analysis (PFA) is a student model that traces predictions of individual students on knowledge components (KCs) using successes and failures [7], which might be helpful for developing effective adaptive technologies. KCs are "acquired units of cognitive function or structure that can be inferred from performance on a set of related tasks" [8]. Each tone can be considered as a KC. The original Performance Factors Analysis model is as follows.

$$m(i, j \in KCs, s, f) = \sum_{j \in KCs} (\beta_j + \gamma_j s_{i,j} + \rho_j f_{i,j}) \quad (1)$$

$$p(m) = \frac{1}{1 + e^{-m}} \quad (2)$$

In Equation 1, m is a logit value representing the accumulated learning of student i on one or more KCs j . β represents the easiness of each KC. s and f track the prior successes and failures of the student on each KC. γ and ρ scale the effect of the observation counts. Equation 2 shows the standard conversion from logit to probability prediction.

Even though prior successes and failures are strong indicators of student learning, tracking the counts of prior successes and failures

Meng Cao, Philip Pavlik and Gavin Bidelman "Incorporating Prior Practice Difficulty into Performance Factors Analysis to Model Mandarin Tone Learning" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 516 - 519

is meaningless for item selection without some rule for what to do with the predictions once they are computed. From the results of PFA model, we can know whether correct or incorrect responses lead to more learning on each KC, but this can't be used to select items since if the success coefficient is higher than the failure coefficient, this implies us to minimize the difficulty and choose practices that maximize immediate success. However, the pedagogical theories we reviewed suggest that it is misguided. Thus, we need to revise the PFA model to capture a curvilinear effect of prior practice difficulty of learning.

To achieve this goal reliable data is needed on the learning functions for 4 tones. We designed an experiment to gather data and planned to use this data to analyze learning as a function of these prior difficulty factors.

2. METHOD

2.1 Participants

325 participants on Amazon Mechanical Turk (MTurk) finished the practice. Participants needed to meet the following criteria: be over the age of 18, have little knowledge of Mandarin tones and no hearing problems, and have successfully completed 100 MTurk tasks previously with 95% acceptance. 70 of them were excluded because of technical problems. 49 of them were excluded as their scores were lower than 0.31, which would mean a 95% likelihood of chance performance. 206 participants were used in the analysis below (Female = 90, Male = 116).

2.2 Stimuli

We synthesized varied stimuli with 4 tones, 3 syllables (ma, mo, and ya), 3 durations (400ms, 800ms, and 1200ms), 3 expansions (1.0, 1.4, and 1.8), and 2 gender voices (male and female). There were 216 stimuli. The fundamental frequency (f_0) were controlled in MATLAB and overlaid onto syllables in PRAAT [9].

2.3 Procedure

We used the Mobile Fact and Concept Training System (MoFaCTS) which is a flashcard (one-step drill) learning system that can be used to schedule experimental practice [10]. Participants needed to finish 216 trials with feedback. For each trial, they needed to listen to the tone and choose the correct answer. If the answer was correct, the system would show the feedback and then immediately went on to the next trial. However, if the answer was incorrect, the system would replay the tone and showed the correct answer for 6 seconds.

Table 1. Learning conditions

Factor	Conditions	Trials 1-72	Trials 73-216
Syllable	6	e.g., ma	e.g., ma, ya
Duration	6	e.g., 400ms	e.g., 400ms, 800ms
Expansion	6	e.g., 1.0	e.g., 1.0, 1.4
Gender	6	e.g., male	e.g., male, female

The dependent variable was learners' correctness on the trials. The experiment was a mixed between and within subject design. Tone was a within-subject variable while other variables were mixed between and within subject variables. Participants were randomly assigned to one of the 24 learning conditions (see Table 1). On each factor, there were 6 conditions counterbalancing the stimuli participants learned. The factors listed in the table did not vary

while other factors varied. For example, in a condition on syllable, participants first learned 72 trials of *ma* (3 duration \times 3 expansion \times 2 genders \times 4 tones = 72), then they learned another 144 trials which randomly mixed the first 72 trials of *ma* and another 72 trials of *ya*. The goal of this design was to look for both learning from repetition of items and transfer to similar items.

2.4 Statistical Analysis

To create a model to determine the optimal practice difficulty, we incorporated prior practice difficulty into the PFA model to see how the difficulty influences learning gains for successes and failures. Since we didn't have a quantitative theory on the exact shape of the inverted U relating learning and difficulty, we used the simple quadratic equation below because it was computationally tractable compared to alternatives. In Equation 3, y represents the effects of learning from each item, where x represents the difficulty level of the item.

$$y = ax^2 + bx \quad (3)$$

Then the new formula of Difficulty PFA model takes the following form (see Equation 4). We track the effects of prior difficulty level using quadratic equations for both prior successes and failures to replace the counts.

$$m(i, j \in KCs, s, f) = \sum_{j \in KCs} (\beta_j + \gamma_2 x_{s,i,j}^2 + \gamma_1 x_{s,i,j} + \rho_2 x_{f,i,j}^2 + \rho_1 x_{f,i,j}) \quad (4)$$

We have emphasized that keeping an optimal level of difficulty of items might be beneficial for learning. The new model can help us find at what difficulty level, learners' performance improves the most. To use the new model, we first did logistic regression to determine the difficulty of the items (Model 1 below). Then we formed the new PFA model (Model 2 below) which incorporated the prior practice difficulty and compared it with the original PFA model. Following this, we used the coefficients to graph of the optimal difficulty level for each tone. All analyses were completed in R, with source code available from the corresponding author.

3. RESULTS

Table 2. Results of logistic regression

Model	Predictors	Mean test fold R ²	Mean test fold RMSE
Model 1	Tone:Duration:Gender:Syllable:Expansion	0.1148	0.4604
Model 2	Tone:Duration+Diffeffectcor1:Tone+Diffeffectincor1:Tone+Diffeffectcor2:Tone+Diffeffectincor2:Tone	0.1872	0.4388
Model 3	Tone:Duration+CF..tonesubcor.:Tone+CF..tonesubincor.:Tone	0.1841	0.4397

Model 1 (see Table 2, where the R code : indicates interactions) was done to get a constant coefficient for all the items to represent their difficulty score. The higher the coefficient, the easier the item. Model 2 was the new model we created which incorporated prior practice difficulty into the Performance Factors Analysis model. Tone by duration interaction was used as the intercept to represent the prior easiness of the KCs. *Diffeffectcor1* is the sum of difficulty

scores of prior successes. *Diffeffectcor2* is the sum of squared difficulty levels of prior successes. Similarly, *Diffeffectincor1* and *Diffeffectincor2* represent prior failures. Their interaction in the model with tone means tracking of each of the 4 tones as individual KCs. Model 3 was constructed according to the original PFA model. *CF.tonesubcor.* and *CF.tonesubincor.* tracked the counts of prior successes and failures on each tone. In order to assess whether the results of the models could generalize to an independent data set or not, we did 10-fold cross validation 100 times for each model and calculated the mean of R^2 and RMSE (see Table 2). The crossvalidated test fold R^2 of Model 2 was larger than Model 3, and the crossvalidated test fold RMSE was smaller than Model 3 which all indicated that Model 2 had better performance than Model 3.

Figure 1. Plots of logit change given the difficulty level for each tone. The x-axis represents the difficulty score, and the y-axis represents the logit change. Given the difficulty value x , we can get y amount of change in logit per trial.

Our next step was to use Model 2 to infer the optimal difficulty level of items for learning. Since logistic regression tracks an underlying linearly increasing strength, “the logit”, we decided to use this as the quantity we wanted to be maximal for each repetition of practice. While more complex questions can be asked, such as considering the gain/cost, for this initial work we wanted to show only the gain function as a proof of concept that this method could be used to create pedagogically significant models.

From the results of Model 2, we used the coefficients of each parameter and computed the logit function increase or decrease as a function of difficulty on each tone (see Table 3). Then we plotted the functions and found the maximum values of logit change (see Figure 1) for the range of difficulty in the data. For Tone 1, the change in logit per trial is the largest when the difficulty score is 0.86, For Tone 2, Tone 3, and Tone 4, the difficulty scores are 0.75, 0.54 and 0.60, respectively.

Table 3. The function logit change of difficulty level

Tones	Range of difficulty (x)	The function logit change
Tone 1	0.519 to 0.940	$x*(0.276*x-0.26*(x)^2) + (1-x)*(-0.27*x+0.19*(x)^2)$
Tone 2	0.421 to 0.756	$x*(0.19*x-0.20*(x)^2) + (1-x)*(-0.19*x+0.19*(x)^2)$
Tone 3	0.160 to 0.742	$x*(0.45*x-0.57*(x)^2) + (1-x)*(-0.12*x+0.014*(x)^2)$
Tone 4	0.211 to 0.800	$x*(0.59*x-0.68*(x)^2) + (1-x)*(-0.13*x+0.017*(x)^2)$

4. DISCUSSION

In this study, we collected learners’ Mandarin tone learning data on Amazon Turk and found that tone and duration were the most important factors predicting learners’ performance, but many different factors determined difficulty for items of each tone. Then we replaced counts of prior successes and failures with the quadratic functions of the difficulty level of prior practice. Crossvalidated results showed that the performance of the revised “PFA-Difficulty” model was better than the original PFA model. Even though the quantitative benefit was not large, it is very meaningful for later item selection. Different tones have different optimal difficulty levels. For the four tones, the optimal difficulty scores were 0.86, 0.75, 0.54 and 0.60, respectively.

While we show the computation to produce these curves from the model coefficients for each tone, it may not be obvious how the underlying correctness and incorrectness each show interpretable curves as a function of difficulty. Figure 2 shows the correctness and incorrectness curves separately for tone 1 (plotted using either the 2 correctness coefficients, top, and the 2 incorrectness coefficients, bottom). As we can see, only the correctness curve (top) has an inverted U-shape individually. This follows the “Goldilocks principle” and the zone of proximal development theory which all propose that practices should be neither too easy nor too hard [11,12]. The result also makes intuitive sense, since it is commonly understood that practice needs to match a student’s current level of proficiency.

The incorrectness curve in Figure 2 (bottom) is less intuitive, but it helps to remember that PFA’s adaptive nature means that in some cases, and for our data here, the coefficient for failure is negative. The figure means that when a learner gets it wrong, the penalty is monotonically more negative as difficulty is less. This again makes

sense since we might expect that if a student gets the easiest items for a KC wrong, the proficiency estimate for that KC should be adjusted more negatively.

Figure 2. Correctness curve (top) and incorrectness curve (bottom) for Tone 1. The x-axis is the difficulty score, and the y-axis is the logit change.

The PFA-Difficulty model considered the difficulty level of items instead of simply counting. The quadratic function means that the relationship between practice difficulty and learning is nonlinear [5]. According to this perspective, there should be a point between maximum and minimum difficulty where learning is maximal. This may be true for multiple reasons, for example, keeping item difficulty at an intermediate level could help to maintain learners' motivation and persistence at a higher level [13].

Our finding in this study is the first step to construct an "optimal" adaptive training system. To achieve adaptive training we need to constantly adjust the difficulty level of items selected in order to keep performance near the pre-defined level [13]. However, the analysis we showed used static difficulty predictions, which means that the curves we computed are not sensitive to changes in performance. In other words, they answer the question of which specific item is optimal overall, but they do not say how the choice of the optimal item also depends on the change of performance due to learning. Intuitively, and in preliminary tests, it seems that we need to input learners' learning rate into the initial model of difficulty, so the curves will predict optimal learning as a function of performance difficulty (which includes both item difficulty and learning) instead of only item difficulty. That is the direction for current work which is out of the scope of this preliminary report.

5. CONCLUSION

This paper incorporated the prior practice difficulty into the PFA model using a quadratic function of the difficulty level and proved that the new model was a little better than the original PFA model. The new model could be considered an update or a variant of the

PFA model which could better track students' learning and provide corresponding guidance. It is particularly useful for item selection when constructing an adaptive training system since it leads to specific predictions about the most optimal item to practice, given a set of possible items for some KC.

ABSTRACT

Parents play key roles in forming their children's trajectories of development. Parental involvement has been studied in early grade reading and math facts' practices. However, their hands-on engagement with children's math problem solving activities, in particular with the goal to develop higher order problem solving skills and promote perseverance behaviors, has not received substantial attention yet. With the goal to understand the dynamic interplay between children's affective and cognitive processes and parents' support, we have collected multi-modal data of multiple parent-child dyads where parents serve as companions for their children while working through challenging math problems at home. In this paper, we report some initial findings with this data which has been annotated with a combination of automatic and manual methods.

Keywords

math problem solving, multi-modal learning analytics

1. INTRODUCTION

Different from math practices, non-routine math problems are those for which no immediate solutions are available. Whether or not one may eventually solve such a problem depends not only on the activation of prior conceptual and procedural knowledge, but also on the mastery of general problem solving strategies, meta-cognitive skills, as well as the habit of mind to persevere through impasses or uncertainties.

Though researchers have explored in-school interventions for supporting development of perseverance [3], and the common core standard lists mathematical perseverance as one of the math practice standards since its inception, it comes however without a clear guideline on how to operationalize it in a real-world school environment with constrained resources.

Lujie Chen, Eva Gjekmarkaj and Artur Dubrawski "Parent as a Companion for Solving Challenging Math Problems: Insights from Multi-modal Observational Data" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 520 - 523

One alternative answer to that challenge is to look for solutions beyond schools. Parents are typically not trained as professional educators, however, from daily interactions they often gain rich insights into their own child's stable traits such as personality, interest, self-efficacy and self-control, which provide valuable information in estimating the child's tolerance to frustration - an important parameter to guide the support.

The ultimate goal of our project is to explore a model of at-home intervention where parents are motivated to engage with their own child in solving challenging math problems on a regular basis. Perseverance habits, though believed to be malleable, take time and consistency to develop. The main challenge in implementing effective interventions is thus the consistency of time investment given the busy schedules of modern parents. We envision a Fitbit¹-like tracking tool that can measure and report a child's exposure to struggle, that can analyze and give feedback on parents' coaching strategies, and that can motivate and engage both the parent and the child by providing data driven analysis to stimulate ongoing conversation, reflection, and improvement.

As the first step toward this vision, we set out to explore the feasibility of the envisioned work flow by collecting and analyzing high resolution observational data of parent-child dyads at home while they are working on challenging math problems together. From those baseline data, we aim to develop a suite of relevant metrics and analytical methods that can facilitate the reflection and improvement for the child and parent. In addition, we explore the opportunities and practical challenges for automating the analysis by leveraging machine learning techniques. This paper reports the first attempt along these lines of investigation.

2. RELATED WORK

Tutorial dialogues with expert tutors have been studied extensively to identify effective tutoring strategies with more recent work contextualizing the students' emotional profiles [4]. In addition, work has been done to study negative emotions such as confusion and frustration when students are interacting with computer systems [1]. Our work builds upon those studies, however with a different goal: to model parents as imperfect tutors and help them to become better, along with their pursuit of promoting perseverance behavior.

¹<https://www.fitbit.com/>

ior in their children via solving challenging math problems at home. Our work also builds on rich mathematical problem solving literature. Though those studies mostly focus on older student population (high school and beyond), their frameworks of math problem solving are still relevant.

3. STUDY PROTOCOL

Children within age ranges of eight to twelve years old (or third to sixth grades) and their parents are recruited from a local community. They meet at least one of the two criteria: (1) The child shows interest in math problem solving; (2) The parent is interested in developing math problem solving skills in his or her own child. The data were collected at home by parents using a webcam (Logitech 1080P) and digital pen (Livescribe 2GB Echo Smartpen).

In each session, the child works through one problem and the parent provides support standing by on the child's side as needed. Parents are advised to choose the problems that are most likely to challenge their children thus inducing a certain amount of confusion or frustration.

4. DATA SET OVERVIEW

Data from 42 sessions were collected, however, data from 6 sessions were excluded due to child's limited amount of exposure to struggles. For the remaining 36 videos, the cumulative duration of is about 307 minutes, with a mean duration of 7.9 minutes per session. The shortest session lasts about 2.7 minutes while the longest one is about 21 minutes.

We used OpenFace [2] tool to extract features related to the child's head movements and rotations (i.e. roll, pitch and yaw), and eye gaze orientations. In addition, we also used the FACET tool to extract estimation of 6 basic emotions as well as confusion and frustration.

We annotate talking episodes for both child (child-talk) and parent (parent-talk). The annotation is done at the utterance level. In addition, we annotate the child's eye gazes which are round trips of child's head poses and eye gaze changes toward his or her parent and back. Based on those annotations of discrete events and intervals, we compute continuous intensity measures derived from event intervals smoothed by Gaussian kernels over time. This measure combines event frequency and duration, so that many short episodes of talking are equivalent to a few long episodes.

4.1 An Example Session

Figure 1 shows one example session with a subset of features (affect estimations for joy, confusion and frustration, writing speed and eye blinks), together with annotation for child and parent's talk and child's eye gazes (presented as intensity measures mentioned above). This session lasts for about 8 minutes. The child was working on a word problem that requires him to piece together the information from the problem and reason through it in order to get the answer. His mother provided moderate amount of support along the way. Details of the progression are as follows:

- Phase A: The child reads the problem out loud during the first 17 seconds;

- Phase B: The child jots down some notes on paper (as seen by spikes in writing speed) and tries to make sense of the information given, while brief moments of confusion and frustration are noted. This episode lasts for about 1 minute;
- Phase C: He continues to reason through the problem, noted by the decrease of eye blinks during this period of time, which might be linked to an increase in cognitive load. This episode lasts about 1.5 minutes;
- Phase D: This phase starts with the parent's suggestion to re-read the problem which results in a moderate amount of intervention where the parent guides the child through the reasoning process and provides confirmation from time to time. The child's eye gaze occurs concurrently with the interaction. It is worthy to note that the child exhibits a substantial amount of persistent confusion and a few brief episodes of frustration. The eye blinks in the first half of the phase are low suggesting high intensity of thinking. This phase ends at the 7th minute where the child completed solving the problem and wrote down the solution.
- Phase E: This is a reflection phase in which the parent suggests an alternative way in solving the problem using a number line. The child listens attentively as manifested by the high intensity of concurrent eye gaze episodes.

It is worth mentioning that the two spikes of joy during phases C and D are indeed "false positives". The child was in a neutral emotional state while speaking sentences with phrases such as "adding eight" which was mistakenly picked up by the affect detector as smiles, possibly triggered by the activation of two joy/happiness related facial action units "cheek raiser"(AU6) and "lip corner puller" (AU12).

5. RESULTS

In this section, we present preliminary analysis of the data set, mainly based on the manual annotations of the dialogue interactions of the parent-child pairs, as well as each individual child's eye gaze events. Where necessary, we incorporate automatically derived features such as the emotional states.

5.1 Parent-child verbal interaction patterns

Figure 2 shows the ratio between the amount of the child's talk and parent's talk summarized at session levels, grouped by subjects. This ratio is a proxy for the amount of parents' intervention during the problem solving process. For example, a session where the child is driving the process is expected to have a higher ratio whereby for sessions in which parents take control are likely to have lower ratios. This is the case for subjects A002 and A003, who are siblings coached by the same parent that tends to spend a large chunk of time working through problems with the child at each detailed step. On the contrary, the parent for subject A004 seats back and allows her child "struggle" first and only intervenes as necessary. When intervening, she often gave high level guidance and brief feedback along the way. Also of note, there are between-session variations for the same subject as the case for subject A005. This could possibly be explained by the varying challenge levels of the problems. If

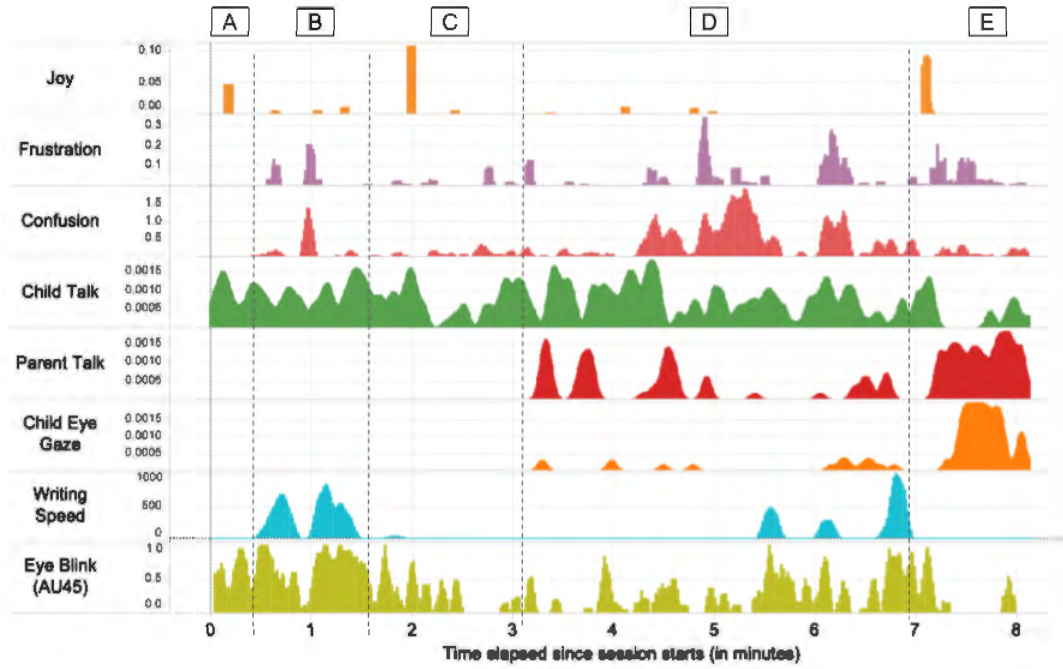

Figure 1: An example session illustrating the evolution of emotional profiles (Joy, Frustration and Confusion), parent and child’s talking episodes, event intensity, writing speed and eye blinks estimation, within the context of problem solving phases from A to E.

Figure 2: The ratio between amount of child-talk and parent-talk per session, grouped by subjects. The vertical axis is logarithmically scaled.

the problem is relatively easy, the child does not need much help and the ratio is high, otherwise, parents need to offer more hands-on help which drives the ratio down.

5.2 Child Gaze Analysis

Gazes are natural ingredients of inter-personal communications which may carry rich meaning and trigger a variety of responses. During the problem solving process, the child may use gazes to express confidence, confusion or frustration, or signal the need for support. Here, we use 524 instances of individual child’s gazes toward their parents as “anchoring points” to infer their cognitive and affective states, as well as the parents’ response patterns. Since gazes

are closely related to the verbal interaction patterns between the parent and the child, we differentiate gazes that occur when the child is the driver of the conversation (“talking gazes”) and those that occur when the parent is talking and the child is listening (“listening gazes”). However, if we note that a child looks at his or her parent without any accompanying talking episodes, and possibly is waiting for an approval or a confirmation response from the parent, we then label those as “approval gazes”.

5.2.1 Gaze Type Distribution

Figure 3 summarizes the gaze-type distribution by subject. It is not surprising to see that talking gaze accounts for the majority of most subjects except for subjects A002 and A003, which could be attributed to the fact that their parent was in the “drivers’ seat” for the majority of time, as revealed by the child-parent talk ratios in Figure 2. As noted, “approval gazes” are relatively rare, and they may be completely missing for some subjects such as A002, A004 and A005.

5.2.2 Analysis of Talking Gazes

For 295 talking gazes, we further annotate whether the child’s utterances are displaying reasoning which are suggestive of deep thinking processes or they are simply reading out loud the problems or describing the procedures such as solving an equation. Furthermore, for those talking gazes to which parents responded within 5 seconds ($n=203$), we annotate whether or not the feedback that the parents gave indicated positive confirmations. Examples of positive feedback are those with key words such as “okay”, “good”, “yes”, “you are right” etc.

Figure 3: Relative frequencies of gaze types, grouped by subjects.

Figure 4: Proportion of talking gazes where child displays reasoning.

5.2.3 Whether a Child is Displaying Reasoning?

Figure 4 shows the likelihood that a child is displaying reasoning given a talking gaze, aggregated for each subject. As shown, for subjects A004 and A005, they are more likely than others to display reasoning. Interestingly, as noted in Figure 2, those two subjects are the ones with above-the-average child-to-parent talk ratio. The connection is not clear however, because these subjects also exhibit a more mature problem solving personalities, and are thus conduct more independent thinking, all the while their parents' decision to stay back forces them to think more on their own.

5.2.4 Whether Parent Gives Positive Feedback?

In Figure 5 we summarize the likelihood of a parent giving a positive response to the child's talking gaze, grouped by

Figure 5: The likelihood of the parent giving positive feedback when they respond.

subject. We note that the parent for subject A005 tends to give more positive feedback than others. It may suggest that the child is progressing nicely or that the parent chose to be more encouraging than average. Regardless of the reason, positive reinforcement like this is likely to have a positive effect on the child's experience, encouraging them to take on more challenging problems in the future.

6. DISCUSSION AND FUTURE WORK

In this paper, we reported data collection and preliminary analyses of 36 sessions of math problem solving by primary school children obtained from 7 parent-child dyads recorded at home by parents. We found that even with simple metrics derived from child and parent talking patterns and eye gazes, we may probe insights into a child's problem solving process when supported by a parent. Specifically, we were able to obtain session-level estimates of the amount of parents' support being offered by looking at the talking patterns. We were also able to get a deep understanding of a child's overall cognitive processes and emotional experience from a set of analyses anchored on the child's gazes. Future work will take those analyses to the level of moment-by-moment, so that we could have a better understanding of the dynamic interplay between parents' real time decisions in terms of the timing and the types of support, and the child's responses and experiences. Ultimately, the research presented in this paper will help develop real-time assistance tools for both the parent and the child, in order to guide both towards more effective home practice experiences.

ABSTRACT

We analyze gender differences in performance assessments and student satisfaction data for nearly 9,000 students enrolled in undergraduate work-integrated learning (WIL) programs in a large North American university. Our analysis leads to two main findings. First, women receive slightly higher performance appraisals from their WIL employers. Second, men appear to be more satisfied with their WIL experiences, especially with compensation, networking opportunities and the ability to make meaningful contributions, while women appear to be happier with the availability of employer support.

1. INTRODUCTION

The gender gap in Science, Technology, Engineering and Mathematics (STEM) is well-documented: studies have shown that fewer women obtain STEM degrees and continue with STEM careers. Some researchers found that work experiences drive attrition more than other factors [5, 7]. However, as noted by Kauhanen et al., [8] while research on gender differences focuses on later career stages, *early* career experiences can greatly affect subsequent career choices. To fill this gap, we investigate gender differences in early engineering careers. We observe that work-integrated learning (WIL), or co-operative (co-op) education, has become part of undergraduate engineering curricula worldwide. In WIL programs, students alternate between classroom study terms and work terms. These work terms correspond to students' first experiences in the engineering workplace.

Our analysis is enabled by access to unique datasets, covering a year of WIL performance appraisals and student satisfaction data for nearly 9,000 undergraduate engineering students in a large university. Our main findings are as follows. In terms of perceived competencies, women tend to receive higher performance appraisals from their WIL employers. In terms of satisfaction, a focused analysis on a second batch of students suggests that men appear to be more satisfied with their WIL experiences, especially with compensation, networking opportunities and the ability to make meaningful contributions, while women appear to be happier with the availability of employer support. However, these results

should be interpreted with caution: they are based on one year of WIL data from a North American institution, but gender differences are also influenced by cultural factors.

2. DATA AND METHODS

We analyze one year of WIL performance appraisal and student satisfaction data (September 2015 to August 2016) for 8,956 students enrolled in engineering or computer science programs (abbreviated as ENG). At the end of each work term, WIL employers give their student employees an overall evaluation on a 7 point scale (Unsatisfactory, Marginal, Satisfactory, Good, Very Good, Excellent and Outstanding Performance), and a detailed evaluation on 16 criteria listed in Table 1, also on a 7 point scale, grouped into Developing (1-2), Good (3-5) and Superior (6-7), or "N/A" indicating not applicable. The evaluator's gender is unknown. Additionally, students rate their employers from one to ten (ten being most satisfied).

The academic programs within ENG are Computer Science and Engineering (38% of ENG), and Mechanical (21%), Industrial (9%), Electrical (8%), Chemical (8%), Civil (7%), Environment (5%), Nanotechnology (5%) and Biomedical (1%) Engineering. We consider three groups of students: all ENG students, only Computer

Table 2: Gender breakdown by program

Group	Seniority	Students	% Men	% Women
ENG	All	8956	77%	23%
	Junior	3828	74%	26%
	Senior	2144	81%	19%
COMP	All	3381	84%	16%
	Junior	1523	82%	18%
	Senior	693	87%	13%
MECH	All	1843	87%	13%
	Junior	780	83%	17%
	Senior	490	90%	10%

Table 3: Student satisfaction criteria

2. Opportunities to learn or develop new skills
3. Opportunities to make meaningful contributions at work
4. Opportunities to expand your professional network
5. Appropriate compensation and/or benefits
6. How closely was the work related to your academic program
7. How closely was the work related to the skills you are developing at university

Science and Engineering students (abbreviated COMP) and only Mechanical Engineering students (abbreviated MECH). We single out COMP and MECH since these are the two largest programs in the dataset. Since we are analyzing students' work experiences, we measure student seniority in terms of the number of work terms completed rather than the academic level: junior students are those who have completed 0 or 1 work terms and senior students are those who have completed at least 4 work terms. The sizes and the gender mix of the different populations under study are summarized in Table 2.

Additionally, we analyze two semesters of data (4,888 students) from a pilot program run from January to August 2017 to explore students' satisfaction with their work terms. In addition to giving an overall satisfaction score, students provided a score from 1 to 5 (with 5 being most satisfied) for the seven questions listed in Table 3. This dataset overlaps with the other 2015/2016 dataset, but some students from the other dataset have graduated by 2017, and there are new students who enrolled in Fall 2016 and had their first work terms in 2017.

We start by comparing the average overall evaluations of men and women by their WIL employers using the Mann-Whitney test. Then, for each of the 16 evaluation criteria listed in Table 1:

1. We compare the average scores of men and women using the Mann-Whitney test,
2. We use a proportion test to compare the fraction of men and women receiving "Developing", "Good" and "Superior" scores,
3. We use a proportion test to compare the fraction of men and women receiving "N/A".

We chose the Mann-Whitney test because it is suitable for the Likert scale used in performance evaluations. Next, to examine differences in satisfaction from the student's perspective, we use the 2015/2016 dataset to calculate average student's evaluations of the employers and compare them using the Mann-Whitney test (again, because of the ordinal nature of the data). We use the same method on the 2017 dataset to identify significant differences in the seven specific satisfaction criteria (Table 3). We repeat each analysis on all, junior and senior students in ENG overall, COMP, and MECH. We use a P-value of 0.05 for all tests.

3. RESULTS

3.1 Workplace Performance Evaluations

Table 4 shows gender differences in all of ENG in the overall performance rating and in the 16 evaluation criteria. We report results of the Mann-Whitney test for the differences of means as well as results of the proportion tests for the fractions of students whose skills were rated as "Developing", "Good", "Superior" and "N/A" (recall Section 2). Furthermore, Table 5 shows the Mann-Whitney tests separately for COMP and MECH, and for juniors and seniors. For statistically significant differences, we report the absolute difference (for the Mann Whitney test) or the percentage difference (for proportion tests), and specify M or F to indicate whether the number was higher for men or for women; hyphens indicate no statistically significant difference. We omit the proportion test results from Table 4 as they produced similar trends as the Mann-Whitney results shown.

We start with the overall performance rating. According to Tables 4 and 5, women receive higher overall ratings in all of ENG and in MECH, but there is no significant difference in COMP, and there is no significant difference between any group of senior women and senior men.

Next, we examine the 16 evaluation criteria. Table 4 shows that in all of ENG, women are rated more highly (and more likely to be rated "Superior") than men on most criteria. Table 5 shows similar trends for both junior and senior women. On the other hand, all men and junior men are rated more highly on resourcefulness and entrepreneurial orientation, but this trend does not persist in senior men. We see no difference in ability to learn and problem solving. Furthermore, the percentage of men who received "N/A" for teamwork, ethical behavior, appreciation of diversity and interpersonal communication is significantly higher than the percentage of women.

Zooming in on COMP, Table 5 shows that all men, junior men and senior men are rated more highly than women on entrepreneurial orientation, with other criteria showing no difference (especially for junior women) or some differences in favour of women (especially for senior women). On the other hand, there are no significant differences in entrepreneurial orientation in MECH. Furthermore, similar to COMP, MECH women are rated more highly than men on several criteria, especially senior MECH women.

3.2 Satisfaction of Students

Table 6 shows significant differences in students' overall satisfaction with WIL using the 2015/2016 dataset; we use the same notation as before. Men appear to be more satisfied in all of ENG and all of COMP. Breaking down by seniority, senior men in all of ENG and in MECH give higher satisfaction scores, but other groups do not show any significant differences.

Table 4: Statistically significant differences between evaluation scores received by men and women in ENG overall

Finally, Table 7 shows significant differences in students' overall satisfaction and the seven detailed satisfaction scores using the 2017 dataset. Overall satisfaction is again higher for all ENG men, but this trend does not carry over to any subgroups. COMP women (but not senior women in isolation) give higher scores on availability of employer support, with other satisfaction criteria either showing no difference or a difference in favour of men. In particular, men appear more satisfied than women with opportunities to develop their professional network and do work more closely related to their academic program. Additionally, junior and overall ENG men report more opportunities to make meaningful contributions than women. Senior COMP men's average scores for receiving appropriate compensation are 0.23 higher (on a scale of 5) than senior COMP women's, which is the highest reported statistically significant difference of means in this analysis.

4. DISCUSSION AND CONCLUSIONS

In terms of workplace evaluations (Table 4 and 5), we found that women tend to be evaluated more highly than men. One possible

explanation is that women who decide to pursue male-dominated degrees are likely to be highly qualified; e.g., one study found that more men than women with low high school mathematics scores pursue STEM degrees [6]. Specifically, we found that women tend to be evaluated more highly on written, oral, and interpersonal communication. Similarly, Wang et al. [15] found that girls are more likely to possess *both* high mathematical and verbal abilities, and boys are more likely to demonstrate higher mathematical abilities relative to their verbal abilities. We also note the higher evaluation scores women receive on teamwork. A recent report on collaborative problem solving from the Programme for International Student Assessment (PISA) similarly found that girls outperform boys in collaborative problem solving in several countries [11]. This difference suggests the need for further investigation, especially with the growing awareness of the importance of collaborative efforts, even in traditionally competitive fields such as STEM [3].

On the other hand, we found that men in computing are perceived as having a stronger entrepreneurial orientation than women. Re-

lated work on risk-taking presents conflicting reports on how risk averse men and women are [10]. There is also recent work that analyzed STEM alumni and found that the university under study produced fewer female entrepreneurs [1]. Given the importance of entrepreneurship in today's economy, it is interesting to note that any group, men or women, receive higher evaluations in this area.

In Section 3.2, we discovered gender differences in students' evaluations of their WIL experiences. Men appear to be more satisfied, especially with opportunities to make meaningful contributions at work, expanding their professional network, and working on topics related to what they learned in the classroom. Additionally, senior men in computing were more likely to report receiving appropriate compensation than women. These results agree with prior, largely qualitative, work on gender differences in workplace experiences. In particular, prior work found evidence of men receiving more opportunities (including to network and contribute meaningfully to their work) and fair compensation [2, 12, 13, 14, 4].

In our analysis of students' evaluations of their employers, the only difference in favour of women was in the availability of employer support, observed mainly in junior women in computing. Assuming that "employer support" is related to "mentorship", this result does not fall in line with prior work that found women to receive less mentoring than their male peers [2, 9]. These differences are important to examine further as they may impact young engineers' career trajectories: there is evidence that dissatisfaction over pay and working conditions can explain the higher rate of attrition for women in STEM as compared to men [7].

ABSTRACT

There are various types of learning aids available to students while solving a problem in an online learning platform, Mastering Chemistry. Among the learning aids, we investigated two that had high usage: *Hints* and *Provided Solutions*. The main research question was how student learning aid usage differed between higher and lower performing students. To answer this question, we explored clustering students by performance metrics into higher and lower performers, and then looking at each group's process as they solved a problem. This method can be used to explore individual differences at a broad level as to how students go about solving problems.

Keywords

Learning aids, individual differences

1. INTRODUCTION

Research on problem solving has provided evidence that children and adults can use a variety of strategies for solving problems.^{1,2} These strategy differences result in different paths through the problem; for example, some students may choose to attempt the problem immediately, others to first request a learning aid, or following an incorrect attempt to immediately reattempt vs. to request a learning aid before reattempting.

One influence on strategy differences may be the performance level of the student, with higher performing students taking one strategy, and lower performers following a different one. For example, prior work has shown expert children use their knowledge in a more efficient way than novice children.³

This idea forms the following exploratory questions: How do differently performing students use learning aids? Do they have different strategies when solving a problem? An online learning platform, Mastering Chemistry, offers *Hints* and *Provided Solutions* as learning aids to students to help them during formative assessments. But they can also be used to avoid doing the more difficult work of solving a problem oneself. Higher performing students might be more motivated to solve the problem themselves, a relationship which could either be characteristic of higher

performance or lead to higher performance (doing more challenging work leads to better memory encoding⁴). Do higher performing students use hint and solutions differently than lower performing students?

1.1 Prior work on learning aid timing

In Mastering Chemistry, students choose when to request learning aids. As previously mentioned, differences in when students request a learning aid could either be characteristic of higher performance, or it could lead to higher performance. Indeed, a great deal of prior work has examined the timing of feedback and its effect on learning.^{5,6,7,8,9,10} In this work, a contrast is usually made between *immediate* feedback, given immediately after a student's response, and *delayed* feedback, given minutes, hours, or longer after a student's response. There are conflicting results about which timing of feedback is more effective for learning⁵, though it seems that delayed feedback may be more effective for high achieving students while immediate feedback is more effective for low achieving students⁶. However, timing in terms of receiving feedback prior to submitting a response to a problem vs. after responding, as well as feedback in a more natural setting in which students choose when they receive feedback, has been less studied. Thus, this work also takes an initial step toward examining the relationships between individual differences in the problem-solving process, the timing of feedback before and after submitting a response, and student performance.

2. METHODS

2.1 Sample

Two semesters in 2017-2018 of a university chemistry course taught by a single instructor were chosen for this analysis. The course was chosen because all assignments and problems had the same course implementation settings, rather than varying implementation settings between assignments, so that students' incentives to use available learning aids would not vary as a result of the implementation settings. There was a total of 1896 in the sample across both semesters, with 946 students in one semester and 950 in the other semester.

2.2 Procedure

This exploratory analysis takes the following approach to answer the research questions presented in the previous sections. First, students are segmented into 2 groups, higher and lower performing students. Segmenting students was done with k-means clustering with the following variables for each student: performance (measured by percent correct on first try), persistence (measured by percent correct on all problem parts), conscientiousness (measured by percent problem parts submitted), and consistency (inverse

Andrea Davis, Yun Jin Rho and Daniel Furr "Individual Differences in Student Learning Aid Usage" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 528 - 531

variability of percent correct on first try). Then, a process analysis examines how higher and lower performing students navigate and solve a problem, and when in the process they open hints and request solutions. The process analysis was carried out using the R package bupaR¹¹. Using this package, raw data were transformed into event log data, and then mapped to show average transition frequencies and transition times between actions, as a student went about solving a problem. Analyses were carried out at the problem level.

3. CLUSTERING STUDENTS

Students were clustered into two pre-defined groups, using the following metrics that were expected to be related to performance:

- performance: percent correct on first try
- persistence: percent correct on main parts of the problem
- conscientiousness: percent main parts of the problem submitted
- consistency: inverse variability (1 - scaled variability) of percent correct on first try. To correct for variability decreasing as the number of attempted problems increases (students' total number of attempts varied), consistency was calculated from a random sample of 12 attempted problems. The inverse was taken so that the direction of this metric would be higher for better performing students, matching the other metrics.

Figure 1. Plot of groups resulting from k-means clustering

Prior to performing k-means clustering, all variables were scaled to have a mean of 0 and a standard deviation of 1. The plot of the groups resulting from k-means clustering is shown in Figure 1, and the group means are shown in Table 1.

Table 1: Group means for higher and lower performers

	Higher performers	Lower performers
performance	0.573	-0.921
persistence	0.560	-0.901
conscientiousness	0.122	-0.196
consistency	0.304	-0.488

4. PROCESS ANALYSIS

Process maps (Figures 2-5) are shown for higher and lower performers, and examining a) relative frequency of actions and b) time between actions at different stages in solving a problem. Relative frequencies of action were calculated by counting the frequency of transitioning from Action A to another action divided by the total number of transitions from action A. Thus, the sum of relative transitional frequencies from one action to all others that followed should be 1. Because problems in the Mastering learning platform are largely designed to be easy (formative assessment), we focused only on student process for more difficult problems. Specifically, using the problem difficulty metric provided by the Mastering learning platform, we excluded problems that fell below the median problem difficulty.

Figure 2. Process map for lower performers

Figure 3. Process map for higher performers

Figure 4. Time between actions for lower performers

Figure 5. Time between actions for higher performers

Examining first the relative frequency of actions at different stages of solving a problem (Figures 2-3), it appears that lower performers request hints before attempting to answer a problem slightly more often than higher performers (17.51 vs. 15.51). However, higher

performers are *more* likely to request a hint following a wrong response (7.9 vs. 5.9), whereas lower performers are more likely to request a solution following a wrong response (1.95 vs. 1.31) or following a hint (18.69 vs. 5.95). Further, higher performers on average take more time before requesting a solution following a wrong response (3.62 vs. 2.49 minutes) or a hint request (3.45 vs. 2.06 minutes), suggesting they are spending more time thinking over the problem before they request the learning aids. These patterns suggest persistent and conscientious behavior by the higher performers; namely, the higher performers overall seem to use learning aids to solve a problem to completion, rather than simply to get the answer and move on to the next problem.

5. CONCLUSIONS

An exploratory process analysis of learning aid usage revealed different patterns of learning aid use by higher and lower performers. While students were clustered based on metrics related to their responses to problems and not based on any measures of learning aid use, the process analysis found patterns of learning aid use that are suggestive of persistence and conscientiousness in higher performing students. These patterns of use may also lead to better learning, as they suggest deeper processing and better memory encoding, though it may be that higher performers are more highly motivated, which causes both a different pattern of learning aid use as well as better performance. Further work examining the timing of learning aids in terms of before vs. after submitting an incorrect response may disentangle these possibilities, as well as provide evidence-based guidance for when to make hints and solutions available to students in an online learning platform.

ABSTRACT

Online educational discussion forums allow learners to expand their understanding of key concepts through interacting with peers. However, instructor interaction with forums does not scale well with large and/or busy forums. We introduce graph-based methods for centrality and clustering using post text and user ID in online educational discussion forums. We use the centrality methods HITS and PageRank to identify important and central topics on the forums, and we use the clustering methods Clauset-Newman-Moore (CNM) and spectral clustering to group posts by topic. We demonstrate that these methods can be used at scale to identify important and central topics of discussion that can be brought to the instructor's attention.

Keywords

graph-based methods, natural language processing, online discussion forums

1. INTRODUCTION

Online discussion forums are useful tools for supplementing both online and in-person learning because they provide opportunities to ask questions to instructors remotely and to discuss class topics with peers. However, discussion forum management can be arduous and time-consuming. Post topics and categories typically must be assigned manually by participants or moderators, topic search is often limited to string matching, and meta-scale metrics on forums and communities are not readily available. Thus, despite the scalability of delivering instruction through online courses such as MOOCs (massive open online courses), monitoring and using discussion forums effectively does not scale; rather, instructors and course staff must manually keep track of the forums and attempt to gauge student interest and/or difficulty with course topics.

The structure of these forums, which contain various con-

Glenn Davis, Cindy Wang and Christina Yuan "N-gram Graphs for Topic Extraction in Educational Forums" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 532 - 535

nected entities such as questions, answers, users, and topics, relates naturally to graph representations. This paper focuses on using graph constructions of online discussion forums to develop methods for answering two important research questions: 1) What are the most central topics of discussion within the forum? 2) How can we assign categories/topics to individual discussions and posts?

To answer these questions, we introduce a new method for creating *n-gram-based graphs* that contain nodes representing n-gram tokens extracted from posts, connected to nodes representing users and the posts themselves. This graph construction allows us to model the relationship between the contents of each post and the greater overall environment of the discussion forum, including related posts and users. We then use centrality methods to find the most important topics being discussed in the forum and use clustering methods to group communities of posts that discuss similar content.

2. RELATED WORK

[1] used network measures from discussion forums as features for automatically assigning forum participation credit. [5] applied social network analysis to discussion forums from two MOOCs to analyze whether centrality metrics are associated with course performance. These approaches give good baseline methods for graph extraction from educational discussion forum data. However, the network measures that they extracted were fairly limited and focused on participant centrality. We build on their work to explore extraction of more complex relationships and different entities as nodes.

[8] generalized methods from [4] and presented a robust comparative evaluation of different edge weight schemes and centrality measures, as applied to word sense disambiguation. They developed an unsupervised algorithm that constructs a graph given a sequence of words and possible labels (word senses) for each word, where the vertices are labels and the edge weights are dependency scores between word senses. Once the graph is constructed, scores are assigned to vertices using graph-based centrality measures to determine the most likely set of labels for the sequence. We use the idea that textual unit similarity can be used as edges in a graphical representation of a body of text to motivate our construction of n-gram graphs.

3. DATASET

We use the publicly available StackExchange dataset¹. This dataset includes all user-contributed content from over 150 StackExchange discussion forums, with detailed information about user interactions. We use the Posts table for our analysis and extract the columns Body (the body text of a post), Id (the ID number of a post), and OwnerUserId (the ID number of the user who made the post).

We focus on two StackExchange subdomains, Academia and Statistics (referred to from here as Stats). Academia provides a moderately-sized dataset for local CPU computation, with 81,906 posts from 18,640 users. The Stats subdomain provides a more focused and pedagogical approach for our problems, as it is larger and more heterogeneous in both user expertise and topic distribution. However, as the Stats subdomain was too large to compute locally, we extracted the most recent 19,725 posts included in the dataset, which spans from 2017-12-07 to 2018-05-05 and includes 9,094 users.

4. GRAPH CONSTRUCTION

We create two different n-gram-based graph constructions to model our two research questions. In order to find the most central topics of discussion, we model discussion forum data using an *N-gram Graph*, where relationships between n-gram nodes are defined by which users use these n-grams in posts. Then, to assign categories and topics to individual discussions and posts, we create a *Post Graph*, where relationships between post nodes are defined by containing similar n-grams in the text body. The specifics of the graphs are defined below.

4.1 Preprocessing

Since both of our graphs are n-gram-based, we first extracted the most important n-grams, which we call “top terms”, for each post in our dataset. To generate these top terms, we used *Tf-idf* (term frequency-inverse document frequency) weighting over all the n-grams in each post body. This weighting assigns higher importance to the terms in each post in relation with the frequency of the term in the post and the scarcity of the term in other posts. We represent the main topics of discussion for each post by the five terms with the highest *Tf-idf* scores. For both the N-gram Graph and the Post Graph, we create a node for each n-gram that appears in these five top terms for at least one post in the dataset.

For the n-gram graphs created from the Academia subdomain, we represent each post by the five most important unigrams, which extracts terms such as “publish”, “mentor”, and “student”. However, we found that unigrams were not sufficient to capture important topics of discussion in the Stats subdomain, as many technical terms are more than one word in length. Thus, for the Stats subdomain, we instead computed the top terms for each post using the *Tf-idf* scores over both unigrams and bigrams, allowing us to extract top terms such as “bonferroni correction”, “mean”, and “probability measures”.

¹<https://archive.org/details/stackexchange>

4.2 N-gram Graph

To create the N-gram Graph used to model the most important topics addressed in the forums, we first modeled the StackExchange data as a bipartite graph. We created n-gram nodes as described above and user-id nodes for each unique author. We drew an edge between a user-id node and an n-gram node if the user had at least one post where that n-gram appeared as one of the five “top terms”. This bipartite graph, which we call the *User ↔ N-gram Bipartite Graph*, captures the relationship between users and the contents of their posts.

Using the User ↔ N-gram Bipartite Graph, we then folded the graph to create an N-gram Graph that contained only n-gram nodes. In this folded graph, we drew an edge between n-gram nodes if they shared an edge to the same user node in the User ↔ N-gram Bipartite Graph. This yielded a text unit graph similar to those constructed in [4] and [8], except we use network interactions as edges instead of similarity scores. In the N-gram Graph, n-gram nodes that appear in posts by multiple users will have an edge between them. Thus, n-gram nodes corresponding to terms that are discussed by many different users will have a high degree. We then apply centrality methods to identify important and central topics (n-grams) in our network. We apply this procedure to create both an Academia N-gram Graph and a Stats N-gram Graph.

4.3 Post Graph

To create the Post Graph used to determine similarity between posts based on topic, we again modeled the StackExchange data as a bipartite graph. We created n-gram nodes as well as post-id nodes for each unique post. For each post-id node, we drew an edge to the n-gram nodes representing each of its five “top terms”. We call this graph the *Post ↔ N-gram Bipartite Graph*.

Using the Post ↔ N-gram Bipartite Graph, we folded the graph to create a Post Graph that contained only post-id nodes. In this folded graph, we drew an edge between post-id nodes if they shared an edge to at least one n-gram node. We then apply clustering methods to group the post-id nodes into communities defined by their main topics of discussion. We apply this procedure to create both an Academia Post Graph and a Stats Post Graph.

4.4 Graph overview

Table 1 contains node and edge statistics for our graphs. We can see that the Academia graphs are much denser than the Stats graphs both before and after folding.

5. EMPIRICAL FINDINGS

5.1 Centrality: Identifying Top Topics

5.1.1 PageRank

PageRank [2] is an algorithm used to rank nodes in a graph by importance. It treats edges as votes and considers each node to be more important if it has many neighbors. Furthermore, it captures the idea that a “vote” from an important node is worth more, and each edge’s vote is proportional to the importance of the source of its page. We use PageRank on our N-gram Graph to find the most central n-gram nodes.

	Academia				Stats			
Graph	Nodes	Edges	Nodes with degree 0	Nodes with degree > 10	Nodes	Edges	Nodes with degree 0	Nodes with degree > 10
User ↔ N-gram Bipartite Graph	62,765	347,084	0	9,066	66,086	95,267	0	2,308
Post ↔ N-gram Bipartite Graph	126,031	409,530	0	5,776	76,717	98,625	0	1,038
N-gram Graph	44,125	46,984,357	0	38,783	56,992	3,674,828	0	32,718
Post Graph	81,906	55,029,806	61	81,500	19,725	567,729	2,586	14,632

Table 1: Summary statistics for bipartite and folded graphs.

5.1.2 Hubs and Authorities

Hubs and Authorities [6] is an algorithm used to estimate the value of each node’s links to other pages and the value of its own content. These are respectively calculated for each node as its *hub* and *authority* scores. Hub and authority scores are defined via mutual recursion: the algorithm iteratively updates each node’s *hub score* to be equal to the sum of the *authority scores* of each node to which it points, and its *authority score* to be equal to the sum of the *hub scores* of each node from which it is pointed. We use Hubs and Authorities on our User ↔ N-gram Bipartite Graph, with the observation that the n-gram and user-id nodes are analogous to hub and authority pages on the web. That is, we can approximate the value of a user-id node in this graph via its links to frequent and important topics of discussion, and we can approximate the value of an n-gram node as its importance in the forum.

5.1.3 Results

We applied the SNAP² Python implementations of PageRank and Hubs and Authorities on our graphs, in order to rank the centrality of all n-gram nodes. We then identified the highest ranked (i.e., most central) nodes as the most important topics of discussion in each forum. Table 2 shows the top ten nodes identified by PageRank (run on the N-gram Graph) and hub score (run on the User ↔ N-gram Bipartite Graph). Our results show that both centrality measures identify reasonable important topics at face value.

Academia		Stats	
PageRank	Hub score	PageRank	Hub score
paper	user75368	distribution	user8013
student	user53	test	user173082
phd	paper	model	distribution

review	author	correlation	time
professor	journal	variance	probability
work	supervisor	probability	sample
author	professor	sample	correlation
letter	research	series	variance

Table 2: Top ten topics by PageRank and hub score.

Furthermore, our results validate our formulation of n-grams and users as hubs and authorities of the StackExchange network. The nodes with the highest authority scores are all user-id nodes, and the nodes with top hub scores are all n-gram nodes, with the exception of the four superusers shown

²<https://snap.stanford.edu/>

in Table 2. We manually validated that these identified superusers are the users with the top user-generated reputation score over the time periods observed, suggesting that these users are indeed seen by the community as valuable contributors.

5.2 Clustering: Grouping Posts By Topic

Modularity measures how well a given partitioning of nodes captures separate communities, as compared to a graph with the same number of edges and nodes with random connections. Modularity score Q for an unweighted graph G can be calculated by the expression

$$Q(G, S) = \frac{1}{2m} \sum_{s \in S} \sum_{i \in s} \sum_{j \in s} \left(A_{ij} - \frac{k_i k_j}{2m} \right)$$

where m is the number of edges in G , $s \in S$ are groups in the partitioning S , i and j are nodes, k_i and k_j are the degree of nodes i and j , A_{ij} indicates whether i and j are connected.

5.2.1 Clauset-Newman-Moore (CNM)

The *Clauset-Newman-Moore* (CNM) algorithm [3] finds communities by greedily optimizing for modularity. Starting with a partitioning of each individual node into its own community, the algorithm repeatedly joins together the two communities that would cause the greatest increase in the modularity score Q , until $n - 1$ joins have been conducted and all nodes belong to a single community. At this point, the algorithm returns the configuration (with a number of communities between 1 and $n - 1$) that produces the highest modularity score.

5.2.2 Spectral Clustering

The *Normalized Cut Algorithm* [7] is a spectral clustering method for partitioning nodes into communities based on the eigenvalues of the symmetric normalized Laplacian. The Normalized Cut Algorithm finds a partition S of the nodes of the graph that gives the smallest normalized cut value: $NCUTS = \frac{cut(S)}{vol(S)} + \frac{cut(\bar{S})}{vol(\bar{S})}$.

To partition the graph into $k > 2$ clusters, we use the *Simultaneous K-Way Cut with Multiple Eigenvectors* modification to the Normalized Cut Algorithm from [7]. To find the optimal number of communities k , we did a search of values of k from 10 to 1000 and computed the modularity score of the communities found for each k value. We selected the k value that gave us the highest modularity score.

CNM		Spectral clustering	
Community (top terms)	Percentage of total nodes	Community (top terms)	Percentage of total nodes
series times group	27.09%	feature dataset value	42.30%
test training validation	23.88%	density normal parameter	5.26%
distribution sample probability	20.43%	training validation data	1.53%
matrix model variables	11.68%	network cost event	1.25%
size power uncertainty	0.81%	series time time series	1.13%
learning rate minutes	0.64%	sample population mean	1.06%
outliers bias percentile	0.49%	distribution normal	1.04%
		distribution probability	

Table 3: Largest communities generated by CNM and spectral clustering

5.2.3 Results

We used the CNM algorithm and the K-Way Cut Normalized Cut Spectral Clustering algorithm on the Stats Post Graph to cluster posts into communities based on similar topics of discussion. CNM generates 66 communities with a modularity of 0.442, and spectral clustering generates 150 communities with a modularity of 0.550. Notably, both algorithms generate community partitions with a modularity score above 0.3, indicating that significant community structure can be detected in our graph [3]. As compared with CNM, spectral clustering produced an optimal partitioning with a larger number of communities and higher modularity score, indicating more consistent partitioning.

Table 3 shows the percentage of nodes in the largest communities found by each clustering algorithm. From this we can see CNM finds four large communities, each with between 10-30% of total nodes, and all other communities contain <1% of the nodes. Spectral clustering finds only one large community that contains 42.30% of the nodes, and more medium sized communities with around 1% of the nodes.

We represent each community found in the Stats subdomain by the three most frequent top terms for posts in the community. Table 3 shows the largest communities generated by both clustering algorithms, and the representative terms for each community. We can see that the most frequent terms that appear in each community are mostly related to one another.

We find that spectral clustering creates a larger number of communities (150 vs. 66), a higher modularity score (0.550 vs. 0.442), and more cohesive communities of smaller size. Thus, we conclude that spectral clustering is more effective at extracting clusters of posts about similar important topics for an educational discussion forum.

6. CONCLUSIONS

We demonstrate that graph methods for computing centrality and clustering can be used to extract important topics and users from an online education-focused discussion forum. Applying our methods across narrow time slices of the discussion forum could allow for instructors to identify topics that require immediate attention in real time, while applying them to a past (archived) offering of the course would highlight important topics for syllabus revision purposes.

Furthermore, identifying clusters of posts about similar topics allows for automatic link generation between posts within

these clusters, and automatic propagation of instructor interventions to all interested parties. Search functionality for both instructors and learners could also be improved through these clusters.

Finally, though n-gram centrality was most salient for the domains we studied, we could similarly compute graph centrality to other entities, such as users and posts. Such methods can be applied to discussion forums that lack a built-in reputation or point system (in StackExchange, user “reputation” and post “votes”), and instructors could use this information to identify potential teaching assistants or moderators, or to allocate course participation grades [1].

ABSTRACT

The Next Generation Science Standards (NGSS [14]) emphasize inquiry practices that students should master including constructing explanations. Most automated methods for scoring scientific explanations, however, do not detect the specific components involved in constructing explanations in the claim, evidence, and reasoning (CER) format, which is commonly used in science classes (cf. [12]). In this study, we expanded and implemented a data-driven, regular expression-based method to automatically score students' written CER explanations across the domains of Physical Science, Earth Science, and Life Science in the intelligent tutoring system, Inq-ITS. We then investigated the generalizability of our method using a new set of testing data. Results of comparisons between human scores and automated scores indicated high performance for the method when applied to the testing data. Analyses showed that the automated scoring for one domain (earth science) had lower performance relative to other domains. Overall, the fine-grained, data-driven, regular expression-based method yielded high accuracy and more reliable scores relative to human scores. Implications for scaffolding CER writing are discussed.

Keywords

automated assessment, regular expressions, science

1. INTRODUCTION

One of the central practices of scientists is constructing explanations of scientific phenomenon. As a result, documents such as the Next Generation Science Standards (NGSS [14]) emphasize that students should master this practice.. Students, however, face many challenges when constructing written explanations (cf., [12]). It is necessary to support students on these difficulties with written explanations in real-time, which is when students benefit most from help [6]. Unfortunately, human scoring of written explanations can be time consuming and subject to rater bias and fatigue [1]. Automated scoring is a solution to these challenges by allowing for real-time evaluation of students' competencies on constructing explanations [18]. However, most automated methods [2, 7, 10, 11, 13, 17] do not detect the specific components involved in CER writing.

Rachel Dickler, Haiying Li and Janice Gobert "A Data-Driven Approach for Automated Assessment of Scientific Explanations in Science Inquiry" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 536 - 539

1.1 Automated Assessment of Scientific Explanations

Automated techniques for scientific explanations vary in terms of the types of algorithms that are used to score students' writing as well as in the particular aspects of students' explanations that are scored. Methods used to automatically score students' explanations include machine learning techniques [13, 10] and natural language processing (NLP) techniques [2, 7, 8, 9, 10, 11, 17]. These methods have been used to score explanations based on the quality of the scientific content of the explanations [2, 7, 10, 11, 13, 17] and the argumentative components within the explanations [8, 9]. In the present study, we focus on methods that applied the NLP method of Regular Expressions (RegEx; [16]) to score study writing.

RegEX [16] involves the application of pattern matching to identify the quality of writing and has been frequently applied to score students' open responses. Researchers at the Educational Testing Service have applied Regular Expressions to score students' scientific writing for the presence of key concepts within conversations [19]. Li et al. [8, 9] applied RegEX in order to assess students' CER explanations in the intelligent tutoring system, Inq-ITS [4, 5]. Specifically, Li et al. [8, 9] developed fine-grained rubrics that captured various sub-components of student CER statements constructed to explain phenomena in the domain of physical science. The RegEX when combined with a linear regression model had high agreement with human raters for each CER sub-component (kappas > .80).

Overall, it is the use of regular expression with if-then algorithms that has shown the best performance in terms of the automated scoring of sub-components of explanations in the claim, evidence, and reasoning format as implemented within the Inq-ITS system [8, 9]. Studies on this method in Inq-ITS to date, however, have been conducted only within the domain of physical science. Researchers have yet to examine whether this automated scoring method would generalize to other domains.

In the present study, we expand the Inq-ITS automated scoring method (i.e., RegEX and if-then algorithms) for CER explanations from the domain of physical science to the domains of life and Earth science.

2. METHOD

2.1 Participants and Sampling Procedure

2,064 sets of claim, evidence, and reasoning (CER) statements (6,195 total statements) were randomly extracted from the intelligent tutoring system, Inq-ITS [4, 5]. 1047 sets of CER responses were constructed in the domain of physical science

(i.e. the Inq-ITS Density Virtual Lab), 481 sets of CER responses were constructed in the domain of life science (i.e. the Inq-ITS Genetics Virtual Lab), and 536 sets of CER responses were constructed in the domain of Earth science (i.e. the Inq-ITS Lunar Phases Virtual Lab). These CER explanations were written by students in grades 6-8 in middle schools in Oregon, Massachusetts, New Jersey, and New Hampshire. Students completed Inq-ITS labs during their regularly scheduled science class periods (see Table 2 for the number of responses for claim, evidence, and reasoning within each driving question in both the training and testing data sets).

2.2 Materials

Inq-ITS [4, 5] is an inquiry intelligent tutoring system for middle school science in the domains of physical, life, and Earth science. Inq-ITS has virtual labs (i.e., microworlds; [3]) in which students carry out inquiry investigations. Each virtual lab has 3-4 different driving questions over the course of four inquiry stages (asking questions/hypothesizing, collecting data, analyzing and interpreting data, and explaining findings in the CER format). All student actions are automatically stored within log files and actions in the first three stages are scored using educational data mining and knowledge engineering techniques (see Sao Pedro et al. [15] for details). Automated scoring of students' CER explanations in the final stage of the lab is the focus of the present study. We randomly selected one virtual lab topic from each science domain (i.e., physical, life, earth) for the present study: Density (Physical Science), Lunar Phases (Earth Science), and Genetics (Life Science).

The Density virtual labs include three driving question activities: (1) how the shape of the container affects the density of the liquid, (2) how the size of the container affects the density of the liquid, and (3) how the type of the liquid affects the density of the liquid. The Lunar Phases virtual labs also included three driving questions: (1) how the percent of the visible Moon illuminated changes, (2) how the duration of lunar orbit changes, and (3) how the percent of the Moon facing the Sun changes. The Genetics virtual labs included three driving question activities: (1) the Mother's F alleles impact the chance of producing the offspring with red fur, (2) the Mother's L alleles impact the chance of producing the offspring with short fur, and (3) the Mother's H alleles impact the chance of producing the offspring with horns. The present study focused on the automated scoring of students' written claim, evidence, and reasoning responses collected within these virtual lab activities (for 9 driving questions in total).

2.3 Rubrics

The rubrics used by human raters were based on a modified version of McNeill et al.'s [12] rubrics (see Table 1 [8, 9]). There were three primary components of the rubric: claim, evidence, and reasoning. The claim component consisted of four sub-components: independent variable (IV), IV relationship (IVR), dependent variable (DV), and DV relationship (DVR). The evidence component consisted of three sub-components: sufficient evidence, appropriateness of data for the independent variable, and appropriateness of data for the dependent variable. The reasoning component included five sub-components: theory or scientific principle, connection between data for the IV, DV, and DVR and the claim, and explaining how the data support (or refute) the claim. This rubric aims to provide more accurate, fine-grained data on how students develop explanations within

the CER framework [8, 9]. Table 1 displays each subcomponent of CER for the Shape-Density lab.

Table 1. Modified rubric from Li et al. [8]

Component	Sub-component		Points
C	IV (Shape)		0-1
	IVR (Conditions)		0-1
	DV (Density)		0-1
	DVR (Same)		0-1
E	Sufficient		0-2
	Appropriate	IV (Mass + Volume)	0-1
		DV (Density)	0-1
R	Theory		0-2
	Connection		0-1
	Data	IV/IVR	0-1
		DV	0-1
		DVR	0-1

Note. IV = independent variable. IVR = how IV was changed. DV = dependent variable. DVR = how DV was changed.

The rubrics for each activity were modified based on the specific content of each activity. Therefore, the structure of each rubric was the same in terms of the sub-components that were scored, but the specific expressions that were captured for each activity (i.e., IV = shape for the Shape-Density activity) differed based on the content of the virtual lab activity. The generation of specific rubrics for the three driving questions within each microworld took about 10-30 minutes [9].

2.4 Human Scoring

One senior researcher and three research assistants graded students' CER statements. All raters received extensive training on how to use the rubrics with practice responses (not included in the training or testing set). Raters continued to receive training until inter-rater reliabilities on practice responses were above kappa of .80. Prior to scoring, the data was randomly split into two sets: training data and testing data.

For the training data, the first activity from each topic was scored by two randomly assigned human raters independently. Rubrics were reviewed with raters prior to scoring. The inter-rater reliability was above Pearson correlations of .80 for each CER sub-component for each of the first activities for each topic, so disagreements were discussed and resolved, and agreed upon score were used as the "human scores" for the generation of automated algorithms and reliability analyses. The training data for the remaining two activities within each topic were then each scored by one rater independently. For the testing data (i.e., 60 sets of CER responses for each activity), two raters were randomly assigned to independently score responses for each activity. After scoring of the testing data was completed, human-human interrater-reliabilities were computed for each activity (see Table 2), disagreements between human raters were identified and resolved through discussion, and agreed upon scores were used for analyses (i.e., human scores).

2.5 Automated Approach

In prior studies [8, 9] we manually developed regular expressions to detect patterns for each subcomponent of students' claim, evidence, and reasoning (CER) statements within the Shape-Density activity based on a corresponding rubric used by human raters. In the present study, we kept the basic RegEX patterns for each subcomponent for CER, but changed the key expressions as concepts changed in different

activities. It took approximately 3 hours total to generate RegEX for each statement type (C, E, or R) for each activity. The structure of Inq-ITS (i.e., enabling students to first construct their claim and evidence within interactive widgets before writing their claim and evidence) affords identification of the types of potential phrases and structures that students may use in their CER explanations.

Phrases that were identified as semantically similar to the components outlined in the human scoring rubrics were used as the basis for pattern matching in the RegEX. We then used a data-drive approach to modify the expressions based on the words or expressions that students used in their responses in the training data set. For example, the IV in the L Alleles activity in Genetics is “L alleles.” When we looked through students’ responses though, we found some alternative expressions, such as “fur length alleles” and “alleles for hair length.” Thus, we modified the original RegEX (i.e., “\b[Ll]b”) accordingly. We then compared the automated scores with the human scores, looked through the responses to identify where there was a disagreement, noted the variations in the expressions, and then modified the RegEX. We repeated this cycle until we achieved high performance, with correlations above .95 or even 1.00.

Implementation of the RegEX in Python allowed for identifying whether particular subcomponents were represented in students’ statements or not, as well as the accuracy of subcomponents included within students’ statements [8, 9]. In particular, the presence of components at each level (0 points = incorrect; 0.5 = partially correct/present; 0.8 = mostly correct/present; 1 = correct/present) is identified and assigned to a corresponding sub-component. We then used the generated RegEX and algorithms to examine the performance of the RegEX and if-then algorithms when applied to a testing data set (i.e., 60 responses from each activity). This study used Pearson correlations - a commonly used metric [10] - to evaluate the accuracy of the automated scoring.

3. RESULTS

We first examined performance of the RegEX at an aggregated level (across all data sets), then by topic, and finally by driving question within topics. Our analyses revealed that there was extremely high agreement for CER between the humans and automated computer scores when examining scores aggregated across all data sets. The correlations in the training data sets were .99 for claims, .98 for evidence, and .97 for reasoning. The correlations in the testing data sets were .90 for claims, .94 for evidence, and .86 for reasoning.

There was also high extremely high agreement when breaking down claim, evidence, and reasoning scoring by topic (i.e., density, lunar phases, and genetics) with all human-computer correlations above 0.95 for the training data and all correlations in the density and genetics labs above 0.90 for the testing data. However, the accuracy of the automated method was relatively low for the reasoning component of lunar phases ($r = 0.73$). It is important to look at each activity within each topic of lunar phases to understand why correlations were lower for reasoning as compared to the other two virtual lab topics.

Finally, we examined the correlations between human and automated computer scores for each activity within each topic. For the training data, the results showed that all correlations were above 0.95 (see Table 2). For the testing data, all correlations were above 0.80 except for the claim for the Lunar

Phases percent of the visible moon illuminated activity ($r = 0.75$) and the reasoning for the Lunar Phases duration of Lunar Orbit ($r = 0.76$). To further understand these discrepancies, we conducted fine-grained analyses using confusion matrices for the claim sub-components for the percent of the visible moon illuminated activity and the reasoning sub-components of the duration of lunar orbit activity.

Table 2. Correlations by virtual lab activity

Activity	CER	Training		Testing		
		H-C	N	H-H	H-C	N
Density						
Shape - Density	C	0.99	293	0.97	0.97	60
	E	0.98	293	0.95	0.97	60
	R	0.97	293	0.93	0.86	60
Amount -Density	C	0.99	305	0.97	0.95	60
	E	0.95	305	0.94	0.86	60
	R	0.97	305	0.84	0.96	60
Type - Density	C	0.99	269	0.97	0.97	60
	E	0.99	269	0.98	0.97	60
	R	0.96	269	0.90	0.96	60
Lunar Phases						
Visible Moon - LP	C	0.95	140	1	0.75	60
	E	0.97	140	0.97	0.95	60
	R	0.98	140	1	0.81	60
Duration -LP	C	0.99	115	1	0.91	60
	E	0.99	115	1	0.93	60
	R	0.96	115	1	0.76	60
Moon Facing Sun -LP	C	1	101	1	0.95	60
	E	1	101	1	0.89	60
	R	0.98	101	1	0.81	60
Genetics						
F allele-Genetics	C	0.99	100	0.90	0.89	60
	E	0.98	100	0.89	0.93	60
	R	0.98	100	0.83	0.88	60
L allele-Genetics	C	1	100	0.90	0.91	60
	E	0.98	100	0.90	0.95	60
	R	1	100	0.79	0.94	60
H allele-Genetics	C	1	99	0.84	0.93	60
	E	1	99	0.91	0.96	60
	R	1	99	0.87	0.90	60

Note. C = Claim. E= Evidence. R= Reasoning. H-C = Human-Computer. H-H = Human-Human. LP = Lunar Phases.

For the lunar phases visible moon illuminated activity, there were several disagreements between the humans and computer for the claim sub-components of: the change in the independent variable (IVR; $r = 0.35$) and the dependent variable (DV; $r = 0.48$). Further analyses using the confusion matrix for the claim IVR scores assigned by the human and computer revealed that there were 14 cases where the computer gave credit (i.e., 1 point) for the presence of the IVR, but the humans did not).The

confusion matrix for the claim DV scores assigned by the human and computer revealed that there were 10 cases where the humans gave students credit (i.e., 1 point) for the DV, but the computer did not.

For the lunar phases duration of lunar orbit activity, there were several disagreements between the humans and computer for the reasoning sub-components of: theory ($r = 0.29$), explaining data for the DV (Data-DV; $r = 0.66$), and explaining data for the change in the DV (Data-DVR; $r = 0.74$). In terms of the reasoning theory scores assigned by the human and computer, a confusion matrix revealed that there were 24 cases where the computer gave students credit (i.e., 2 points) for theory but the humans did not. The confusion matrix for the reasoning Data-DV subcomponent showed that there were 7 cases where humans gave students credit (i.e., 1 point) and the computer did not give any credit. The confusion matrix for the Data-DVR component showed that the biggest differences in scoring were in 4 cases where the computer gave students' credit (i.e., 1 point) but the humans did not give any credit.

4. DISCUSSION

Overall our findings show that the automated scoring method in Inq-ITS is extremely high performing when applied to new data across different domains (i.e., physical, earth, and life science). In particular, the development of RegEX and if-then algorithms using our iterative method was both efficient and effective in terms of being able to capture student performance on explanations in the CER format at a fine-grained level. Our method therefore extends upon other NLP scoring techniques for scientific explanations (i.e., that captured only the linguistic quality or content of explanations; [2, 7, 10, 11, 13, 17]) because it is able to accurately capture students' competencies on the argumentative components involved in constructing explanations in the CER format. In the future, it would be valuable to explore other data processing methods and their potential for even greater efficiency for scoring written CER.

The findings of this study are promising in terms of being able to accurately assess student performance in real-time in multiple domains at a fine-grained level. Specifically, this automated method can now be implemented within the intelligent tutoring system, Inq-ITS, in order to capture student performance as they are constructing their CER explanations. Additionally, this fine-grained scoring can be used to detect student difficulties with particular components of CER statements and, as a result, allow for real-time scaffolding at a fine-grained level in real time. This automated scoring can also be used to alert teachers at an actionable level using Inq-Blotter, our teacher dashboard.

ABSTRACT

Liberal arts universities possess a vast catalog of courses from which students can choose. The common approach to surfacing these courses has been through traditional keyword matching information retrieval. The course catalog description used to match on may, however, be overly brief and omit important topics covered in the course. Furthermore, even if the description is verbose, novice students may use search terms that do not match relevant courses, due to their catalog descriptions being written in the specialized language of a discipline outside of their own. In this work, we design and user test an approach intended to help mitigate these issues by augmenting course catalog descriptions with topic keywords inferred to be relevant to the course by analyzing the information conveyed by student co-enrollment networks. We tune a neural course embedding model based on enrollment sequences, then regress the embedding to a bag-of-words representation of course descriptions. Using this technique, we are able to predict potentially relevant words that are not in a course's description and surface these words through a real-world recommendation platform.

Keywords

Course search, Inferred keywords, Latent topics, Course2vec, Skip-gram, Higher education, Recommender systems

1 Introduction

The course catalog is often the first resource consulted by current and prospective students when wanting to familiarize themselves with and explore the topical offerings of a university. With many universities offering thousands of distinct courses over the span of several years, browsing through the description of each is untenable. Instead, classical information retrieval (i.e., search) using keyword matching is now offered at many, but not all, institutions. A keyword matching approach; however, is only as good as the words the description contains and the users' ability to use query terms that will match. Many course descriptions can be overly brief, omitting topical terms from the descrip-

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 540 - 543

Figure 1: Design process for the enhanced search

tion that are nevertheless contained in the course. Furthermore, for novice students, it can be difficult to gauge the similarity of courses in different departments because of the superficial differences in how different disciplines describe the same material.

In this paper, we seek to mitigate the shortcomings of topic omission and non-standardized keywords across disciplines in catalog descriptions by leveraging the regularizing power of machine learned embeddings. We apply neural embedding models to historic sequences of student course enrollments in order to embed courses into a space regularized by abstract features, or concepts, associated with courses. We then regress from this space to the space of course descriptions in order to add semantics to the course vector space. These semantics become the keywords which can be added to an enhanced university course search. Our approach is closer to the user experience of an information system but using machine learning techniques more commonly seen in collaborative-based models. This adding of keywords to an object could be framed as a form of topic modeling. Motz et al. [3] provide an approach in this vein most relevant to ours, in which they use students' course enrollments as a signature with which to learn themes of studying using Latent Dirichlet Allocation (LDA). We substitute LDA with the more contemporary machine regularization of skip-gram models [2] and take the work further by conducting a user study ($N = 75$) in which students at a university were asked to rate relevancy of keywords to courses they had taken, generated from the embedding model and other baselines (e.g., random within and outside of description words). Measuring the degree to which our model's inferred keywords correlate with student perceptions of relevance, the results suggest a probability threshold above which predicted out of course description keywords can be chosen and be expected to be more relevant to students than the random within description baseline. Furthermore, we close the research loop by integrating this modeling process into a larger design scheme (Figure 1) leading to the deployment of this enhanced course

Figure 2: A prototype of the course search feature before model tuning and user testing

search feature in a live course recommendation system linked to by the campus’ Office of the Registrar website.

2 Models

Our approach to generating inferred course keywords comprises of three fundamental modeling elements: (1) a vector representation of courses learned from enrollment histories (2) a bag-of-words representation of course catalog descriptions (3) a model that translates from the enrollment-based representation to the catalog-based representation. This is essentially a machine translation, not between languages [1], but between a course representation space formed from student enrollment patterns and a semantic space constructed from instructors’ descriptions of the knowledge imparted in each course.

2.1 Course2Vec

The course2vec [4] model involves learning distributed representations of courses from students’ enrollment records throughout semesters by using a notion of an enrollment sequence as a “sentence” and courses within the sequence as “words”, borrowing terminology from the linguistic domain. For each student s , a chronological course enrollment sequence is produced by first sorting by semester then randomly serializing within-semester course order. Then, each course enrollment sequence is trained on like a sentence in a skip-gram model. In language models, two word vectors will be cosine similar if they share similar sentence contexts. Likewise, in the university domain, courses that share similar co-enrollments, and similar previous and next semester enrollments, will likely be close to one another in the vector space. Course2vec learns course representations using a skip-gram model by maximizing the objective function of context prediction over all the students’ course enrollment sequences.

It is important to stress that our method of producing a course vector from enrollments (i.e., course2vec) does **not** use any course description information. It is based only on sequences of course IDs, with no natural language used. The generalizing principal is that patterns of student collective course taking can produce representations of courses containing abstract concepts of relevance to student course search. The trick to exploiting this is to associate these abstract concepts with concrete keywords, accomplished by the translation model, explained in the section after the next.

Table 1: Course Keyword Groups Example	
Course: STAT 135 - Concepts of Statistics	
Course Description: A comprehensive survey course in statistical theory and methodology. Topics include descriptive statistics, maximum likelihood estimation, non-parametric methods, introduction to optimality, goodness-of-fit tests, analysis of variance, bootstrap and computer-intensive methods and least squares estimation. The laboratory includes computer-based data-analytic applications to science and engineering.	
Model Sorted (All): regression, statistics, random, statistical, estimation	
Model Sorted (Description): statistics, statistical, estimation, variance, tests	
Model Sorted (Non-Description): regression, random, real, linear, discrete	
Random (Description): course, engineering, includes, methods, computer-based	
Random (All): diverse collection, topics problems, year credit, planning research, user interfaces	

2.2 Bag-of-Words Representation

We represent course catalog descriptions using the simple but indelible approach of bag-of-words and its variants. To create a course description vector, the length of the number of unique words across all items serves as the dimension of the vector, with a non-zero value if the word in that vocabulary appears in the description. We experiment with the description vector as binary, tf-idf, as well as a custom weighting scheme such as tf-bias that controls the granularity of keywords represented.

2.3 Translation Model

Our premise is that there are useful concepts learned in the embedding of course2vec, but these concepts left in abstract vector form contain no explicit semantics. To associate the patterns learned in course2vec with semantics, we apply a translation from the course2vec vector to its respective natural language course description vector.

We use a multinomial logistic regression to conduct this mapping, where the skip-gram based course vectors are used as input and the corresponding descriptions of every course as bag-of-word encodings are the multi-hot labels being predicted. After this model is trained, the probabilities of each word in the vocabulary belonging to a skip-gram course vector can be computed by consulting the softmax probability distribution over the entire vocabulary. Using this probability distribution, it is now possible to find the high probability words predicted based on course2vec which are NOT in the course description. These words can subsequently serve as inferred keywords in our enhanced course search.

Logistic regression is used to represent translation between languages because the spaces being translated to and from are linear vector spaces (skip-grams have no non-linear activations). However, in case the translation between spaces in the course domain is a non-linear one, we also evaluate a single hidden layer neural network with non-linear activation as a candidate translation model in our optimization experiments.

Step 2: Rate each keyword's relevance to the course content, based on the following scale (this scale is only for your personal reference):

1 Not Very Relevant 2 Not Very Relevant 3 Not Very Relevant 4 Not Very Relevant 5 Very Relevant

Statistics 105: Concepts of Statistics
You took the course during Spring 2019 with:

Keyword	Relevance
11	1 2 3 4 5
12	1 2 3 4 5
13	1 2 3 4 5
14	1 2 3 4 5
15	1 2 3 4 5
16	1 2 3 4 5
17	1 2 3 4 5
18	1 2 3 4 5
19	1 2 3 4 5
20	1 2 3 4 5

Figure 3: Keyword rating form for given course

3 USER STUDY

Through offline model selection based on 144 experiments attempting to optimize heuristics expected to correlate with relevancy ratings, we settled on a regression model and corresponding hyperparameters that maximized our custom model evaluation metric. Following the experiment driven model selection, we follow up with a human judgment evaluation to better gauge how the model results are aligned with students' perception of relevance. A user study was conducted during which students were asked to rate keywords belonging to five different groups:

1. *Model Sorted (All)*: Top five overall keywords as predicted by the model.
2. *Model Sorted (Description)*: Top five words in the description in order of likelihood as predicted by the model.
3. *Model Sorted (Non-Description)*: Top five words not in the description in order of likelihood as predicted by the model.
4. *Random (Description)*: Five random words from within the description.
5. *Random (All)*: Five random words across all collective descriptions.

An example of these keyword groups for a particular course are shown in Table 1. The Random (All) words represent a baseline relevancy score. We expect the description groups to perform much better than this baseline and desire that the model predicted non-description words are also better than randomly selected words. The random (description) group provides the second benchmark to compare our model sorted non-description group to, quantifying how much value our enhanced search proposes to add on top of the catalog description.

3.1 Study Design

Undergraduates were recruited from popular university associated Facebook groups to participate remotely in exchange for a \$10 Amazon gift certificate. Study participants logged into the main *AskOski* recommender site using their university credentials in order to access the survey. Figure 3 shows the rating form for one course with its corresponding unique keywords from each of the five groups randomly shuffled. We intentionally did not show the description and

Figure 4: Keyword group rank vs relevancy

requested students to not look them up and rate solely on their experience with the class to prevent bias in keyword ratings whereby a student may be tempted to simply rate a word as relevant only if it appeared in the description.

For every keyword, students were asked for their five point Likert scale agreement with the following statement: *This keyword is relevant to the course*, where a score of 1 corresponded with *Not Relevant At All* and a score of 5 corresponded with *Very Relevant*. A total of 75 students participated in our study, rating a total of 8,355 keywords.

3.2 Results

The average student relevancy ratings of keywords from each of the five groups is shown in Figure 5. All three Model Sorted groups, and the Random (Description) group, scored between a 3 (neutral) and 4 (relevant) in keyword relevance. Selecting keywords at random from the entire vocabulary, Random (All), scored a 1.836 (below "Not Very Relevant"), representing students' lower bound for perception of relevance. All pairwise differences between keyword groups were statistically significantly reliable at $p < 0.005$, after applying a Bonferroni correction for multiple (10) Wilcoxon rank sum tests, except between Model Sorted (All) and Random (Description) groups which was not statistically separable ($p = 0.019$).

The benefit of the model-based approach in terms of improving relevance of chosen keywords can be quantified by the difference in ratings between the random within-description selection group, Random (Description) - 3.612, and the model-based within-description selection group, Model Sorted (Description) - 3.916. A breakdown of the proportion of each rating level by group can be seen in Figure 5. The majority (51%) of Model Sorted (Description) keywords received a 5 rating (Very Relevant), compared to Random (Description), for which 42.1% were Very Relevant. Model Sorted (Non-Description) has a much lower proportion of Very Relevant ratings (31.5%), but still considerably higher than the Random (All) baseline, with 7.3%, and with 62.3% of keywords in its group receiving the lowest relevancy rating as compared with Model Sorted (Description), that received 20.6% Not Relevant ratings.

Figure 5: User study relevancy ratings by keyword group

The way in which student relevancy ratings played out with respect to the within-group ranking of the keyword based on model probability is shown in Figure 4. The average relevancy rating (y-axis) by rank (x-axis) is plotted for each of the three model-based approaches. Since the two random models do not involve any model probabilities, they also are not associated with a rank. Therefore, they are represented in the plot as horizontal lines corresponding to their averages. The Model Sorted (All) trend shows the highest average ratings at rank 1, followed by an apparent asymptote down to just above the average random within-description level. Differences in ratings between these two at each rank level are statistically significantly reliable except at ranks 3 and 4. The Model Sorted (Non-Descrip) trend is initially above Random (Description) at rank 1, but then dips down and asymptotes to a Neutral average ratings value of 3.

A premised benefit of the predictive model was to surface relevant keywords that are not in a course’s description (Non-Descrip). If we were to highlight inferred keywords, we would like to show only keywords that are “better” than words chosen randomly from the description, or at least not show words statistically significantly worse. The Model Sorted (All) ratings are statistically reliably higher than Random (Description) at ranks 1 and 2. We use this information to tailor our strategy for when and how many inferred keywords to display in the production version of our enhanced course search feature.

3.3 Selecting keywords to display in search

With an improved understanding of the relevancy of the model’s predicted keywords, we discuss how to leverage this information towards improving the search feature by updating our inferred keyword selection criteria. In the prototype, the criterion was to always display the top 10 model keywords, which did not exclude words in the description. We continue to not restrict the display of keywords from the description, as showing them could serve the added benefit of a topic category source for reference. Thus, we choose Model Sorted (All) as the focus of this analysis.

We leverage the observation that Model Sorted ratings correlate with rank to investigate how well the underlying model probabilities of those words correlate with student relevancy ratings. If there is a correlation, then the probabilities, along with a threshold, could be used to dynamically determine which words should be included as inferred keywords on a per course basis. To conduct an analysis comparing model

probabilities to user ratings, we normalize these two sets of ratings using Z-scores and then average them by Model Sorted rank. We find a substantive correlation between probability and rank and would like to choose a threshold of probability from Model Sorted (All), such that all keywords with that probability or above can generally be expected to produce keywords perceived by students to be more relevant, on average, than a word chosen at random from the description. The analysis in the previous section (Fig 4) found that user relevancy ratings for Model Sorted (All) were significantly higher than Random (Description) at ranks 1 and 2. Therefore, we use the probability at rank 2 as the cut-off. Using this probability cut-off, we find 4.32 total words on average expected to be displayed for each course, with 2.33 within-description words and 2.00 non-description words surfaced on average within these semantics.

4 Conclusion

We explored surfacing novel, searchable semantics of a course using an embedding of courses informed by course selection histories, and supported our methodology through a user study to evaluate the relevancy of these keywords. Our experiment contributes both methodologically to the use of embeddings to surface latent semantics and to the design of data-driven information systems in educational settings. Our process of interface prototyping, followed by offline model optimization, user testing, and incorporation of study findings into the production software system can also serve as a design model and guide for other technologies to tune EDM analyses towards better student experiences.

ABSTRACT

This poster/demonstration presents our preliminary efforts to explore learning data and model predictions by mapping them into objects in a three-dimensional space. Our work is related to the area of visual analytics, where machine learning or other analytic techniques are combined with interactive data visualization to promote sense making and analytical reasoning. The demonstration consists of interactive VRML models generated from the DataShop Geometry9697 dataset. The initial results indicate that in spite of some limitations the approach allowed to identify from only the observations distribution specific knowledge components that could be targeted for model refinement.

Keywords

Visual analytics; Dimensionality reduction; Closing the loop between research and practice.

1. INTRODUCTION

The visual inspection of learning curves plays an important role in the discovery of anomalies in learning models [1,10]. In principle, learning curves exhibit a smooth decrease of error rates as a function of the increase number of learning opportunities [11]. When anomalies are visually detected (flat curves, curve spikes, slope increases), they are interpreted as hidden non-obvious knowledge components (KC) [2] that need to be made explicit in the model. Model refinements based on either logistic regression models or hidden Markov models, assume that refinements take place by modifying knowledge component assignments to learning items. However, visual inspection has its limitations, and alternative means of exploring alternative model refinements through computations and model fitness assessments is an active area of research [2].

However, given the need to close the loop between research and practice in order to better embed evidence-based education and training, visual analytics might provide an interesting approach to explore. Visual data inspection is a useful operation at the initial stages of data analysis to provide insights about regularities,

oddities, changes, and trends. But as visual analytics human-in-the-loop process models suggest [12,13], visual information is also important at all stages of data mining refinements [15,16].

Our work is related to the area of visual analytics, where machine learning or other analytic techniques are combined with interactive data visualization to promote sense making and analytical reasoning [5]. Our exploration of visual analytics for educational data mining is preliminary and focuses on initial visual representations such as the relationship between: 1) error rates and learning opportunities, 2) observed and predicted error rates for knowledge components, and 3) observed and predicted error rates for knowledge components as a function of learning opportunity phases. The demonstration consists of interactive Virtual Reality Modeling Language (VRML) models generated from the DataShop 'Geometry Area (1996-97)' dataset [7] using unsupervised, and nonlinear methods. VRML is simply used as a format to support data visualisation, other formats are also possible such as X3D, FBX, or OBJ. The file format for encoding 3D models is independent from the mapping method of an original data set of n -dimensions to a three-dimensions space.

Prior to displaying the data for visual inspection using VRML, the method reduces the multidimensional attribute values of the data source to a three-dimension geometric space exposing object proximity, known object links, and object clusters. The method seeks distance/dissimilarity preservation between the original high-dimensional space and a target low-dimensional space, so that any relationship found between these patterns and any other external variable is due to the existence of interdependencies between that variable and the original descriptors [15]. The purpose is to make all distances comparable, regardless of how many attributes are used. For example, objects 1 and 2 may have 5 attributes in common, but 1 and 3 may have 10. Normalizing by the number of common attributes eliminates the differences when comparing distances computed with different numbers of attributes.

As an exploratory data analysis method, mapping a data set into a three-dimensional space has as a primary objective to reveal patterns in the data that could be worth of further investigation. In spite of the fact that visual inspection is not exempt of biases [4], the dimensions reduction method ensures that the loss of information on all objects pairs similarity distances in the mapping from N to 3 dimensions is minimal, preserving the relative proportional distances as much as possible. For the analysis performed in the current paper, the three-dimensional space was computed using the Sammon's nonlinear mapping method [14].

In similarity with t-SNE [9], data points represented in the space have to be interpreted in their spatial relationships with the other

Bruno Emond and Julio J. Valdés "Visualizing Learning Performance Data and Model Predictions as Objects in a 3D Space" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 544 - 547

data points, leaving undetermined the meaning of individual point values in relation to the space axis. One advantage of the mapping to three dimensions in comparison to a mapping to two dimensions, is the reduction of information loss while preserving visual interpretability.

2. ANALYSIS

The next sections explore the application of visual analytics methods to the representation of relation between: 1) error rates and learning opportunities, 2) observed and predicted error rates for knowledge components, and 3) observed and predicted error rates for knowledge components as a function of learning opportunity phases. The DataShop Geometry9697 dataset [7] is used for the analysis, but more specifically the original model which has 15 knowledge components. Other models from the same dataset range in number from 1 to 15 with a median of 12 knowledge components [8].

2.1 Opportunities As Objects

Figure 1 shows the DataShop learning curve for the opportunities averaged over students. One can easily see that the observations in red and the prediction in blue show a reduction of error rates as the number of opportunities increases.

For our first analysis, we were exploring if the 3D modelling method would show a similar trend and structure. The first analysis used an input data matrix containing 74 opportunity objects (37 observations, and 37 predictions) with 15 attributes (knowledge components) with error rates as values with some missing data. Every opportunity object was linked to its successor (next opportunity). The distances were calculated using the normalized Clark distance [3].

Figure 1. DataShop observed and predicted error rates for opportunities.

Figure 2 presents one view of the analysis. The 3D model shows a large dispersion of observation objects (red) as compared to the predicted values (blue). The specific identification of the object (not visible on the figure) coupled with the successor links indicate that the most dispersed observations are for the late opportunities.

Figure 3 shows the same 3D model but with a zoom near the collection of prediction objects. All the objects are in close proximity to their predecessor and successors, but for the lower right, which is the end of the opportunity sequence, capturing the sudden variability in the predictions as also visible from the DataShop plot (Figure 1). However, it is interesting to note that the learning curve pattern is not clearly visually identifiable from the 3D model. The main reason for this limitation is that each 3D model object captures the variation of its multiple attribute values (average error rates for each knowledge component), while the

learning curve in Figure 1 reduces this complexity to one measure of central tendency (average over all knowledge components).

Figure 2. 3D opportunity objects observed (red) and predicted (blue) with error rates for KCs as attributes.

Figure 3. 3D opportunity objects observed (red) and predicted (blue) with error rates for KCs as attributes. (Zoom on predicted values).

2.2 Knowledge Components As Objects

The second analysis focuses on knowledge components as objects. This input data matrix contains 30 knowledge component objects (15 observations, and 15 predictions) with 37 attributes (opportunities). The matrix cells contained error rate values with some missing data. Every observed knowledge component object was linked to its predicted value.

Figure 4. 3D knowledge component observations (red) and predictions (blue).

The Figure 4 presents the resulting 3D model. A visual inspection of the figure shows that observations (red) are more on the outside than the predictions (blue), suggesting that overall prediction values have more similarity than the observations. The 3D model also displays links of various lengths between knowledge component observations and predictions, suggesting a good fit for

short links. However, this 3D model does not match learning curve anomalies identified with specific knowledge components such as the COMPOSITION-BY-ADDITION in the original AFM model [8]. In the 3D model, the link between the observation and the prediction is not long (bad fit) and none of the nodes stand out of the main visual group of objects. Given that the data suffers from student attrition [6], it is possible that either missing values or high variability or error rates introduce too much noise and creates too much dispersion, so that some of the visual structure is not exposed.

In order to reduce the noise created by the attrition in late opportunities, a new input data matrix was generated by assigning opportunities to classes. Error rates values were split using a piecewise regression method in three opportunity phases: initial (opportunity 1), mastering (opportunities 2 to 7), and attrition (opportunities 8 to 37). This matrix contained 90 knowledge component objects which consisted of each of the 15 observed, and 15 predicted knowledge component error rate values for each of the 3 opportunity phases. Every observed knowledge component object was linked to its predicted value. Figure 5 presents a partial view of this analysis, leaving out the model the prediction objects. In the figure, the red objects correspond to the initial opportunity, the green object to the mastery learning efforts, and the blue objects to the remaining opportunities.

The figure indicates a cluster of red objects on the left and another one the right. The identification of these objects indicates that the objects on the left correspond to the knowledge components with high initial error rates. However, both the mastery (green) and attrition (blue) objects seem to be distributed evenly in the space. The figure also contains directional links going through some of the knowledge component objects for which there is at least a shift towards the left of the 3D model, indicating a learning curve anomaly.

Figure 5. 3D knowledge component observations (KC) with initial opportunity (red), early mastery learning efforts (green), and late learning opportunities (blue). Along the X axis, it is expected that for a given KC, the order of colour from left to right would be red-green-blue.

Table 1 summarizes the main visual features of the knowledge components identified in Figure 5. A visual inspection of the figure indicates that the majority of objects (knowledge components) are ordered from left to right in red, green, and blue, which corresponds respectively to the classes of initial, mastery efforts, and late learning opportunities. However, some knowledge components in the figure break from this pattern, and are labelled with the KC names and arrows linking the learning stages. In agreement with other analysis of this dataset [7], the knowledge components COMPOSE-BY-ADDITION, CIRCLE-RADIUS, and TRIANGLE-AREA have been selected as learning curve anomalies and objects for model refinement [2]. Interestingly, the identification of potential issues was made possible by only looking

at the observations without having to inspect individual learning curves anomalies.

CONCLUSION

This poster/demonstration presented our preliminary efforts to explore learning data and model predictions by mapping them into objects in a three-dimensional space. Some limitations were obvious with the first analysis of the general learning curve over opportunities. However, the inspection of a knowledge component 3D model, where learning phases (initial, mastery, attrition) allowed to identify from only the distribution of the observations some knowledge components that could be targeted for model refinement. The approach seems to be valuable and worth pursuing for the combined analysis of learning data and model predictions. Future work will consist of looking at students' performance to see if the 3D model compares to AFM student parameter values. The approach could also be applied to visually compare alternative models of the same knowledge components set.

Table 1. Knowledge components with error rates change anomaly as identified in Figure 5.

Knowledge component	Initial to Mastery	Mastery to Attrition	Interpretation
COMPOSE-BY-ADDITION	Slight shift to the right	Slight shift to the left	No learning.
CIRCLE-RADIUS	Strong shift to the left	Slight shift to the right	Performance decrease then some learning
TRIANGLE-AREA	Strong shift to the left	Slight shift to the right	Performance decrease then some learning
CIRCLE-DIAMETER	Strong shift to the left	Strong shift to the right	Performance decrease then learning

ABSTRACT

Efficient learning experiences require content to dynamically match a learner's skill; this assumes a fast and accurate assessment of the learner's skill and the ability to update content accordingly. Effective personalized learning therefore involves deriving a performance-predictive mapping between behavioral and environmental factors. Once learned, this relationship can be used to generate new content and to update skill estimates based on the learner's interactions in an adaptive system. To provide proof of concept:

(1) We develop a fast-paced driving video game where the player skillfully navigates a cluttered environment comprising obstacles and collectibles. Game content is generated procedurally and player behavior is recorded in the game—this provides an ideal test-bed for a method aiming to learn such a performance-predictive mapping.

(2) Using blurred occupancy maps of the game's segments, we generate risk-weighted trajectory profiles for each user and segment of the game. Here, we show that these profiles can be used in a regression model to predict in-game performance both within and between game segments. Additionally, these profiles themselves reveal a trade-off between in-game rewards and risks. Successful identification of predictive environmental units within the game provides insight into the mapping between environmental features and performance, while facilitating the process of procedurally generating new, appropriate content in our adaptive system. We show that rapidly assessed measures of risk are highly predictive of both driving performance and reward rate, providing proof-of-concept evidence for the feasibility of a personalized adaptive learning system for this game.

1. INTRODUCTION

A central topic in modern educational research is to determine how best to personalize learning experiences. While mismatched content can lead to inefficient learning, boredom, frustration, and disengagement, well adapted content may lead to Flow state, and learning efficiency [1]. Personalized learning systems require a) a *performance evaluation mechanism*—in order to measure the impact of content features on learner performance—and b) an *adjustment mechanism*—that determines content updates depending on the performance evaluation [2]. Hence, personalized learning systems require the derivation of a performance-predictive mapping between learner's performance and content features. Such a mapping is particularly challenging to derive for complex environments with continuous, real-time user interactions.

We aim to develop a framework to investigate solutions for real-time performance evaluation and content adjustment in a complex environment. Such a framework requires the ability to generate content procedurally with complete control over the content features. It must also be able to provide continuous interactions between content and user, support the data collection related to these interactions, and must be accessible and engaging to a wide audience. We use a driving video game as the learning environment because it fulfills all of these requirements. In addition, driving requires motor control, which is a well characterized domain for understanding general principles of human learning on a computational and biological basis, [3] and it has been used for cognitive training [4]. A driving game might seem unrelated to traditional educational settings (e.g., math quiz); yet, we believe that it provides a fertile ground for research on personalized learning and has the potential to transfer to situations that are more typical in education.

To make the analogy to education clearer, we treat the procedurally generated driving tracks as being composed of a sequence of segments, each of which presents a navigation problem. Segments tap navigation knowledge, and we assume there is a low-dimensional knowledge space that covaries with

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 548 - 551

measurable features of the segments, and performance on these segments. Our goal is to show how to use player performance to the parse the environment into segments predictive of differences in performance, then use the features of these segments to learn which aspects of the procedural generation system most affect segment “difficulty”. The end result is an online segment-wise performance evaluation mechanism that uses segment feature information to predict difficulty, and uses observed performance to estimate skill.

In complex learning environments, like in this driving game, quantifying difficulty needs to integrate performance with respect to all task objectives; because players must simultaneously reduce the risk of crashing while maximizing collectibles, we model difficulty as having risk and reward components. In general, tasks with multiple objectives should manifest trade-offs, which makes simple performance assessments inappropriate. Thus, simultaneous assessment of risk scores and reward rates are essential for investigating the validity of an adaptive system framework that we wish to implement.

1.1 Adaptive System

The flow of the proposed online adaptive system is shown in Figure 1. In the learning environment (here, the driving game), content is procedurally generated, varying key parameters which affect difficulty. This new content is processed to identify performance predictive features of the content by creating a risk prediction map. This map can be used to predict user performance on content and identify ahead of time which sections of the map are likely to be predictive of success (e.g., acquiring collectibles, avoiding collision). After the user interacts with the content, feedback about risk (e.g., proximity to obstacles) and reward (e.g., observed collection rate) is used to update the user’s skill estimate in the trade-off space. In this paper, we focus on *proof of concept* in generating, within the context of driving video game, the risk prediction map and validating its relationship with performance on our segments.

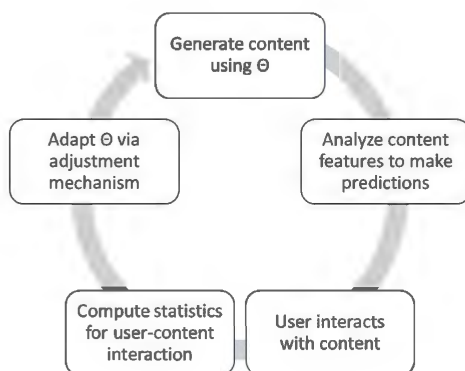

Figure 1. Flowchart of the full adaptive system. Game content is generated by specifying parameters for a generative process. These features have a relationship to the content’s difficulty, and when learned, provide a prediction of performance. After presentation, interaction statistics are calculated and the estimate of the individual’s skill is updated. The skill estimate is used to set new environment parameters, Θ . To learn the relationship between content features and performance, the intermediary relationship between interaction statistics and both performance and content features must be observed.

2. METHODS

2.1 Game Design

We developed a fast-paced driving video game where the player has to skillfully navigate a vehicle through a cluttered environment comprising various obstacles and collectibles (see Figure 2). The vehicle moves forward at a constant speed and the player controls its translational movement by pressing the right or left arrow keys in order to acquire collectibles (by running into them) and to avoid the obstacles which delimit a path to follow. Colliding with an obstacle causes the vehicle to reset at an earlier point on the path with no speed; speed then gradually ramps up over the course of 3 seconds before reaching its constant value. During gameplay, the player’s inputs, trajectory, collectibles collected and collisions are recorded.

The content of the game (i.e., the path to follow, the distribution of obstacles and collectibles, and the visual aesthetics) is generated procedurally. The driving space is composed of a sequence of independent segments, separated by buffer zones which contain no obstacle or collectible. Each segment is generated from a procedural sequence of user inputs describing a timeline of keys (left, right) being pressed and released, for a given duration—this ensures that in principle the segment can be successfully driven. This sequence of virtual user inputs can be characterized by its *variability* (i.e., change in duration and direction across inputs), and its *pacing* (i.e., number of inputs over time) and is used to compute the corresponding *reference trajectory* that a player should follow, taking into account the physical characteristics of the vehicle such as mass, drag and thrust. Obstacles are then placed around this reference trajectory. The minimal distance between obstacles and trajectory defines the *narrowness* of the segment. The minimal distance between obstacles defines the *ambiguity* of the path—when the distance is small the correct path is perceptually salient and there is low ambiguity as to where to drive; when the distance is big it becomes unclear which path to take (see Figure 2). Finally, collectibles are placed directly on the reference trajectory, at critical points of each turns.

Figure 2. Subjective (top) and bird-eye (bottom) view for representative portions of each segment (obstacles in black, collectibles in orange). Each segment represents a distinct statistical profile of our generative game design. A video of the game can be found here: https://youtu.be/gRSX_cOh5-4

2.2 Reward Rate Scores

To quantify a player’s performance on the task of acquiring collectibles for a given segment we use the reward rate score which is defined as:

$$\lambda = (c/t) / (C/T)$$

Where C and T are parameters of the segment and c and t are behavioral data. Specifically, C is the total number of collectibles on a segment and T the fastest possible completion time of that segment; c is the number of collectibles acquired by the player and t is the players' actual completion time. Therefore, λ is a proportion between the rate at which the collectibles were acquired (i.e., c/t) and the highest possible rate for that segment (i.e., C/T).

2.3 Risk Scores

We postulate that an individual's ability to achieve a high reward rate score (λ) is a function of their ability to acquire collectibles while avoiding obstacles. To quantify the individual's interactions with the environment, we compute a risk statistic for their trajectory. This statistic is a function of both features of the environment and the user's behavior. We compute a risk score for each observed player trajectory through the segment, which weights the trajectory by its distance to nearby obstacles at each time point, monotonically resembling the risk of collision. Since collectibles are placed along the reference trajectory used to generate the segment, they reside along points where this function will be low, while space occupied by obstacles and near obstacles is high.

A vectorized bird's eye map of each segment (see Figure 2, bottom) can be used to generate a risk profile for each measured trajectory. Since risk of collision should drop off continuously with the distance between the vehicle and obstacles, a gaussian kernel was convolved with a filtered map containing only obstacles to generate the risk heat map. Then, for each point in a player's trajectory, the corresponding risk value on the map is found in order to construct a risk profile for that trajectory. That is, the risk value of every point in the trajectory. Averaging the risk values across the trajectory provides a unique *Risk Score*.

2.4 Pilot Study Design

For this pilot study, we generated one track that was composed of five different segments; the exact same track was presented to all participants. We generated segments that allowed us to span the space of relevant generative parameters and provided enough samples in terms of observed trajectory length. The first segment is a succession of identical, wide, long turns with no gap between obstacles. Subsequent segments are designed to explore various combinations of features (i.e., different values of narrowness, pacing, ambiguity, variability) and are expected to be of increasing difficulty, culminating with the last segment where perfect performance is only achievable for an expert player. Table 1 illustrates the parameter choices for these five segments.

Table 1. Qualitative descriptions of each segment.

	segment 1	segment 2	segment 3	segment 4	segment 5
Narrowness	low	medium	medium	high	high
Pacing	low	medium	medium	high	high
Variability	low	low	medium	high	high
Ambiguity	low	low	high	low	high

2.5 Data Set

Seven participants played the driving game one to seven times, resulting in 28 sessions with a unique trajectory for each of the five segments; it takes a minimum of 26 seconds to complete a single segment and the longest observed completion time was 138 seconds (on segment 5). The main role for this preliminary dataset is to serve as a testbed for exploring the relationship between the risk scores of a trajectory and the individual's performance in environments generated procedurally from a set of parameters. This understanding contributes to the development of an analysis pipeline whereby these relationships could, in a future step, be exploited by an adaptive difficulty algorithm.

2.6 Analysis

To assess the relationship between risk and reward scores, we looked at a) the relationship between a single segment's risk score and performance and b) the relationship among segments to see whether information from one segment generalizes to other segments. Normally, a regression model predicting a rate would use a Poisson link, however, since the data collected fell mostly in the middle (linear) region of possible values, a log-linear model was used instead, with the log transforming the data to better fit normality assumptions.

Cross-segment predictions could be informative for an adaptive system which aims to predict performance on one segment from the performance on a previous one. The risk scores of each of the 5 segments for each of the 28 sessions were compiled into a matrix (28 sessions x 5 segments) for fitting linear regression models for each segment where the output variable is the log-transformed reward rate score (λ) for each attempt on the segment. We fit the relationship between the risk scores one or multiple segments and the reward rate score of each segment, giving five models with five possible predictors each. Additionally, we look at the specific within-segment cases.

The model search space for cross-segment fits is defined by all combinations of the main effects of risk score for each segment ($2^5 = 32$ possible models per segment). The best-fit model of the reward rate score on each segment was selected using an exhaustive branch-and-bound search algorithm with Mallows' Cp criterion [5]. In the case of gaussian linear regression, Cp values are equivalent to AIC. This procedure is functionally similar to lasso regression by forcing some parameter coefficients to be 0 by not including them when they do not contribute to the fit. Thus, five within-segment relationships and five between-segment models are considered.

3. RESULTS

Linear fits of the relationship between reward rate on a segment and the mean risk score for that segment is shown in Figure 3. We see that overall, the reward-rate is negatively associated with the risk score, characterizing a trade-off. Additionally, this tradeoff varies between segments, with some segments producing different ranges of both reward-based performance and risk-based performance. The coefficients of the risk scores of one segment in the best fit model of the reward rate of another segment is shown in Figure 4. Notably, the risk scores of segments show stronger relationships with the reward rates of segments with more similar features and difficulty (Table 1).

Figure 3. Difficulty is captured through risk-reward trade-off functions. The relationship between the mean risk score on a segment and the log of the normalized reward rate. Each datapoint represents one trajectory through a segment. The slope shows a trade-off between risky behavior and reward-rate, such that incurring additional risk negatively affects the rate at which collectibles are acquired. The slopes present a distinctive notion of difficulty—higher slopes are more challenging in the sense that there is less leeway for trajectory error to preserve performance. Note that the *average performance* per segment does not capture this more fundamental trade-off. In an adaptive system, we target the relationship between segment attribute statistics and the slopes and intercepts of the risk-reward trade-off functions.

Figure 4. Difficulty varies smoothly with task statistics. Matrix showing the coefficients of risk scores in best fit models for cross-segment predictions of reward rates. Each ij -cell represents regression coefficient for predicting reward success on segment j from the risk profile in segment i .

4. DISCUSSION AND FUTURE WORK

Our results demonstrate a fundamental trade-off in difficulty in our driving game, and that difficulty is directly related to the underlying task generative parameters. Moreover, segment-wise performance is predictive of performance on new segments, indicating that there is some lower-dimensional space that indicates skill *across* racing segments. The simple linear models (shown in Figure 3) and best-fit linear models (shown in Figure 4) suggest that in our virtual environment the analysis of the risk profiles of player trajectories on some segments is informative of a reward rate-based performance measure on the same and other segments (R^2 range from 0.58 to 0.74). While measuring reward

rate is slow during online gameplay, measuring risk is fast and relatively easy. This analysis demonstrates we can predict both using only risk scores, which is important during real-time assessment.

Given our ability to diagnose performance, we can incorporate our results into a full adaptive system by using the predicted skill to adjust difficulty. This can be incorporated directly, for instance by having a library of segments that are adaptively selected based on their predicted difficulty for a given user. To incorporate the procedural generation aspect of the game we can sample the generative parameter space to predict this difficulty tradeoff in a hierarchical model. This can close the loop on the adaptive system in Figure 1, by adjusting segment generation based on risk assessment.

5. CONCLUSION

We proposed a framework which makes use of the relationship between features of procedurally generated content and individual performance to generate novel content. Using a modest sample of pilot data collected from a custom-designed driving game, we show that a risk statistic adequately summarizes the interactions between a player and segments of the game. The relationship between these variables reveals a tradeoff between performance and risk in the task. Using this statistic, which can be computed easily online, predictions about performance both on current task and future tasks can be made. In generating an operating adaptive system, the next step will be to learn a model of the relationship between environmental features and these summary statistics to facilitate the adaptive generation of content.

Visualization and clustering of learner pathways in an interactive online learning environment

Daniel Furr

daniel.furr@pearson.com

ABSTRACT

The present study seeks to improve our understanding of how learners interact with assignments in an interactive online learning platform, Revel. First, a means of visualizing learner pathways through assignments is proposed. This tool is then used both to inform choices regarding feature extraction and to interpret the result of applying cluster analysis to those features. Results suggest that characteristic ways of interacting with the online platform include: completing assignments while largely following the designed sequence of activities, completing assignments while deviating more from the sequence, and stopping work before completion of the assignment.

Keywords

interactive learning environment, visualization, cluster analysis, partitioning around medoids, k -medioids

1. INTRODUCTION

Traditionally, active engagement in higher education courses requires learners to spend time reading sections of an assigned textbook. Reading material can reinforce what is taught in class, but learners may be discouraged from reading when the text is difficult to access and is not engaging. The present study explores learner behaviors in an interactive online learning platform, Revel. With Revel, learners are given assignments to be completed before class so that they can arrive to class better prepared to learn. Typically, an assignment covers one chapter, broken into sections. These assignments alternate between learning objects (texts, videos, interactives, etc.) and assessment objects (writing prompts, multiple choice questions, etc.). The assessment activities help the learners to check their understanding. At the end of a chapter, the learners are presented with a more summative assessment of the content.

Though learners within a class will typically see the same online assignments, they likely will not engage with the assignments in the same way. The present study seeks to improve our understanding of how learners may differentially interact with online assignments.

First, a means of visualizing learner pathways through assignments is proposed. This tool is then used both to inform choices regarding feature extraction and to interpret the result of applying cluster analysis to those features. In the end this approach should indicate several characteristic ways in which learners work through the online assignments.

2. SAMPLE

Six introductory psychology classes were taught at the same university. In each class, thirteen assignments were administered with the online platform, and these assignments were similar but not identical between classes. In total there were 761 learners who altogether submitted 8,341 assignments in the online platform.

3. METHODS

3.1 Data

The stream of learner interactions within the online platform was extracted from the platform database. Each interaction may be characterized by the type of object involved and the type of action performed.

The three object types are:

- *learning objects*: the texts, videos, interactives, etc. that make up the instructional aspects of the chapter
- *section assessment objects*: questions posed to the learner following a small set of learning objects
- *chapter assessment objects*: summative questions posed at the end of the assignment

The two actions types are:

- *view*: the learner accesses a learning object or accesses an assessment object without answering it
- *answer*: the learner provides an answer to an assessment object

The assessment objects are multiple choice questions, which may be attempted up to three times. Three points are awarded for correct responses to section assessment objects, while five are awarded for chapter assessment objects. A one-point penalty is applied to reattempts. Instructors are encouraged to incorporate assignment scores into the course grade to bolster learner engagement.

3.2 Visualization of pathways

A learner's pathway through one assignment may be depicted visually. Figure 1 provides an example. In the figure, the actions a learner takes are displayed as connected points, arranged along the

Daniel Furr "Visualization and clustering of learner pathways in an interactive online learning environment" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 552 - 555

Figure 1. Example pathway.

x-axis in the ordered that the learner took them. The shape of the points indicates the type of action: circles for answering and triangles for viewing. The sequence of objects for the assignment is given in the y-axis, and the colored horizontal ribbons divide the plot region according to object type: lighter blue for learning objects, darker blue for section assessment objects, and green for chapter assessment objects.

The example pathway in Figure 1 shows that this learner started by accessing a couple of learning objects two to three times each. Then the learner answered nine section assessment objects in sequence, skipping over several learning objects as they did so. Following that, the learner backtracked to review many of the objects they previously encountered without providing new answers to the assessment objects. Next, the learner backtracked again, viewing some of the learning objects they previously skipped before continuing on through the assignment in sequence.

3.3 Feature Extraction

Reviewing several example pathways as in Figure 1 informed on what features should be extracted from the stream of interactions. Based on this review, the following features were extracted for the 8,341 assignments submissions:

- *sections_viewed*: the percentage of learning objects the learner viewed
- *sections_repeated*: the percentage of learning objects the learner viewed more than once
- *section_items_answered*: the percentage of section assessment objects the learner answered
- *section_items_repeated*: the percentage of section assessment objects the learner answered more than once
- *chapter_items_answered*: the percentage of chapter assessment objects the learner answered
- *chapter_items_repeated*: the percentage of chapter assessment objects the learner answered more than once
- *skip_aheads*: the percentage of transitions between objects in which the learner moved forward in the sequence skipping over one or more objects
- *go_backs*: the percentage of transitions in which the learner went to an earlier object in the sequence

3.4 Clustering of pathways

Cluster analysis is performed to determine what typologies may exist for student pathways through the online assignments. The Partitioning Around Medoids [1] (PAM) algorithm, also known as *k*-medoids clustering, is employed for this purpose. PAM is similar to *k*-means clustering [2], but rather than define clusters by means, it defines clusters by their most representative observation (mediod). An advantage of PAM is that it is more robust to outliers than *k*-means clustering.

For both PAM and *k*-means clustering, it is necessary to prespecify the number of clusters *k*. Clustering methods are commonly used in exploratory analysis where *k* is not known in advance. The choice of *k* may be made by trying several values and selecting the one that maximizes some criteria. The criteria used in the present study is the average silhouette width [3], which provides a measure of how well each observation fits with its assigned group, ranging from zero to one. Averaging this across the dataset provides an overall index of the goodness of fit that may be used to select an optimal *k*.

4. RESULTS

The PAM algorithm was applied for values of *k* ranging from 1 to 7 on standardized (mean-centered and divided by the standard deviation) features, using Euclidean distance as the dissimilarity measure. The average silhouette width was maximized at .24 for *k* = 3 groups. This value for average silhouette width is considered low and suggests a somewhat weak structure regarding the clusters.

Focus will be given to the three-group solution because the greatest support was observed for it. The groups, numbered one through three, consisted of 2,852, 4,832, and 657 observations respectively. Figure 2 presents the (unstandardized) feature values for the representative observations of the groups.

Looking to Figure 2, Group 1 may be characterized as viewing about half of the learning objects, answering about half of the section assessment objects, and answering all or nearly all of the chapter assessment objects. This group also tended to view learning objects more than once, and often skipped ahead or went back in the sequence of objects. For convenience of interpretation, this

Figure 2. Feature values for the representative observations.

group may be labeled *wanderers*, as they engaged with most of the objects but not in an orderly sequence.

Group 2 is similar to Group 1 in terms of the number of objects viewed and answered, but Group 2 less often skipped ahead or went back in the sequence. Their pathway through the assignment was more linear, and for this reason Group 2 may be labeled *arrows*.

Group 3 is characterized as viewing fewer learning objects, answering fewer section assessment objects, and answering few or no chapter assessment objects. Given that the chapter assessment objects appear at the end of the assignments, these points suggest that this group quits assignments part way through. In light of this, Group 3 may be labeled *incompleters*.

A feature of the PAM algorithm is that each cluster is formed on the basis of a representative observation. Similar to the visualization for the example pathway shown earlier in Figure 1, it is possible to visualize the three representative observations as shown in Figure 3. (Note that the three observations are not associated with the same assignment and so have different numbers of objects depicted in the figure.) Naturally, the subplots in Figure 3 mimic the preceding characterizations of the groups; the wanderer proceeded through the assignment in a more erratic path than the arrow, and the incompleter stopped part way through.

5. DISCUSSION

In the present study, a means of visualizing learner pathways through the online assignments was developed and subsequently used to guide in feature selection and interpretation for a cluster analysis. The results of the analysis suggest that learner pathways may be characterized as wanderers, arrows, or incompleters, with these group memberships encapsulating how much and how orderly assignments were completed. Future research may

investigate the relationships between group membership and outcomes such as course performance.

The result of a cluster analysis will naturally be a function of the features included, and so it must be considered that if different features were extracted for these data, then the clusters revealed would also differ. Further, given that the value for average silhouette width for the selected clustering scheme indicated weak structure, it is likely that an improved set of features could be devised. A better feature set could include information about the correctness of answers to assessment objects, the amount of time spent on the different types of objects, or when the work is done in relation to the due date. Future research may investigate these additions.

Filtering non-relevant short answers in peer learning applications

ABSTRACT

Applications that adopt peer instruction and active learning make use of short student answers as a learning opportunity: they take some answers as topics of discussion in class, or select answer rationales from peers to foster self-reflection on the learner's own rationale to a question. However, experience with these applications reveals that some answers are irrelevant, inappropriate, or could even be offensive, and must therefore be filtered out. Automatic identification of these rationales is the topic of this research. We introduce an easy-to-implement approach based on standard text classification techniques, namely bag of words and vector space models, and show its effectiveness for filtering irrelevant answers.

Keywords

Student response systems, Short answer grading, Vector space model

1. INTRODUCTION

Contemporary student response systems (SRS) [4, 2] allow students to provide free-text answers to short open-ended questions. These open-ended questions better enable teachers to capture student's higher level of understanding than close-ended questions [8]. Answers to open-ended questions can serve for in-class discussion and feedback, such as in Socrative [6]. They also serve in out-of-class peer-instruction, as in DALITE [1] where other student's answer rationales are presented to students to nurture self-reflexion on a student's own rationale.

However, experience with SRS shows that a small proportion of the answers given by students are inappropriate and should not be presented to their peers. Filtering out these answers by reading through them is a daunting task. For example, with over 100k answer rationales currently in our

own system, DALITE, the task is highly demanding. With answers that are shown in-class, as with Socrative, pre-screening would take up too much teacher attention and would not scale well to large classes. An automatic means to filter unwanted answers is therefore paramount to such SRS. The goal is to identify student answers that are deemed irrelevant or inadequate for in-class discussion or for inducing student self-reflection on the topic.

This problem is similar to spam-filtering to the extent that it is a binary classification to filter undesired answers, but it also draws from the problem of automatic short answer grading to the extent that desired answers are related to a topic and to a specific question. While the topic of automatic short answer grading dates back to the 1960's and is still an active field of research (see [3, 5, 10] for some recent advances), we propose an approach to filter unwanted student answers that relies on a simple Bag of Words (BOW) method to classify undesired answers from relevant ones.

2. PROPOSED FILTERING METHOD

Building on the idea that a binary relevant/non-relevant classification is the goal and on the principle that correct answers will dwell on a specific topic, the proposed method rests on the principle that irrelevant student answers will contain words that are unrelated to the ones of the relevant answers. In that respect, an irrelevant answer is expected to be close to orthogonal to all other answers in a vector space model [11].

Examples of non-relevant answers are, for eg.:

Books for sale
idk (for "I do not know")
I think thats what it is because i am guessing
Who knows, man. It's gotta be constant
four more years!
.
a (for choice a)

Vincent Gagnon, Audrey Labrie, Michel Desmarais and Sameer Bhatnagar "Filtering non-relevant short answers in peer learning applications" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 556 - 559

As can be seen, answers are often very short, but not always. They are sometimes humorous or sarcastic, or simply expressions of frustrations or disengagement. But they are characterized by a vocabulary that is unrelated with the questions domain: physics and ergonomics in our two corpora. Yet, the vocabulary used is generally non-specific to

the domain of the question, which is the assumption behind the proposed approach.

To measure the general orthogonality of an answer, we average the cosine of each answer with all other answers. Given a document-term matrix of n student answers (documents) by t terms, $\mathbf{A}_{n \times t}$, the average cosine of answers d_i in corpus D is defined as:

$$\overline{\cos}_D(d_i) = \frac{\sum_{j \in D} |\cos(d_i, d_j)|}{|D|}$$

where $|D|$ is the corpus size and $|\cos(d_i, d_j)|$ is the absolute value of the cosine between answers d_i and d_j .

To create the term-document matrix, $\mathbf{A}_{n \times t}$, we apply the common practice of word stemming and spell correction. The `tm`¹ package is used for this purpose [7]. The term-document matrix is also transformed using the standard TF-IDF calculated from the corpus.

2.1 Answer relevance classification

The next step is to use the average cosine, $\overline{\cos}_D(d_i)$, to determine if an answer is relevant or not.

We can see from Figure 2 that the distribution of the average cosine for relevant and non-relevant answers is bimodal. Figure 2's distribution corresponds to a single corpus, but both corpuses show the same bimodal pattern. This observation leads to a simple approach to determine the non-relevant answers based on clustering.

Given that non-relevant answers are a small portion of all answers and their average cosine is always lower than the large majority, they tend to cluster around and above 0. We explored the k-means clustering algorithm on the average cosine dimension and find that for values between 2 and 10 clusters, the lowest cluster leads to a relatively stable set of answers. Therefore, the cluster with the closest value to 0 is considered as the non-relevant set of answers. For this study we chose the value of 4 for the number of clusters.

3. DATA SETS

Two corpuses are used in this study. They cover two contexts of use and, to a certain extent, two extremes cases: a small data set with multiple valid open text answers, and a larger data set of rationales to a specific answer choice in a multiple-choice question.

The first corpus is small and representative of the context where answers must be filtered in real-time as they come in. The second corpus is from a peer learning environment where filtering can be conducted off-line. The objective of this environment is to avoid presenting self-reflective rationales that are non-relevant. The first corpus is typical of *Socrative* whereas the second one is from *DALITE*. Another factor that differentiates the two corpuses is students were anonymous in the first context whereas they were not in *DALITE*.

Figure 1: Corpus 1: usability issues with an MP3-CD player device.

Table 1: Inter-judge agreements

	Corpus 1	Corpus 2
Number of non-relevant texts found by Judge 1	11	286
Number of non-relevant texts found by Judge 2	10	297
Inter-judge agreement (Kappa)	95.0 %	97.0 %

Corpus 1. The first corpus is a small set of answers to a single question: “What are the usability issues with the CD-player device”. The device is shown in Figure 1 and has a fair number of problems over many dimensions, from *guidance* [9] to requirements engineering. The question was proposed to a class of approximately 150 students and the students answered through the *Socrative* application. Since there are multiple good answers, the answers often reported multiple issues with the devices. Answers were segmented into single-issue texts by two teacher assistants. Inter-judge reliability was computed using Cohen’s Kappa statistic for two judges who classified answers as relevant or not. As shown in Table 1, the inter-judge agreements are nearly perfect.

Corpus 2. The second corpus contains a much larger number of student answers and covers eight questions. Segmentation of answers into issues addressed is not relevant in this context. The answers are taken from a college-level physics class.

General statistics on the two corpuses are reported in Table 2.

¹<https://cran.r-project.org/web/packages/tm/tm.pdf>

Table 2: Corpus statistics

	Corpus 1	Corpus 2
Questions	1	8
Answers	71	2054
Students	90	367
Non-relevant answers ratio	12.7 %	13.8 %

Table 3: Answer filtering results

Method	F_1 scores	
	Corpus 1	Corpus 2
Average Cosine	0.842	0.839
3-words rule	0.250	0.797

4. RESULTS

Figure 2 shows the distribution of average cosines for relevant and non-relevant answers. The non-relevant answers do have an average cosine that is generally close or equal to 0.

The F_1 classification results of the experiments are reported in Table 3. F_1 scores are calculated considering non-relevant answers as Positives, since the filtering aims to recall non-relevant as opposed to relevant answers (note that using relevant answers as Positives would give different scores).

The results are broken down by the methods described and compared with a simple baseline that is actually used in DALITE which consists in classifying answers that contain 3 words or less as irrelevant.

5. CONCLUSION

We propose a simple-to-implement, unsupervised approach to filter out undesired short and open student answers. Undesired answers typically occur in student response systems such as peer learning environments, for eg. DALITE, or in classroom app., for eg. Socrative. The approach is intended to be effective in a context where some answers are collected, but they are not labeled and no correct answer is provided either. Moreover, the approach is intentionally tested with a small dataset because this is also often to be expected in practice. It is compared with a trivial rule based on the number of words that, while parsimonious and effective, misses some undesired answers.

Results show that the approach improves on the simple rule, in particular for Corpus 1 which corresponds to the Socrative context and where the rule performs poorly. A smaller improvement is found for the peer learning environment of Corpus 2. Moreover, the F_1 score shows that not all irrelevant answers are filtered.

Nevertheless, the simplicity of the approach makes it an attractive means to address the undesired answer filtering issue in practice.

ABSTRACT

Many existing studies analyzing log data from online learning platforms model events such as accessing a webpage or problem solving as simple binary states. In this study, we combine quality information inferred from the duration of each event with the conventional binary states, distinguishing abnormally brief events from normal or extra-long events. The new event records, obtained from students' interaction with 10 online learning modules, can be seen as a special form of language, with each "word" describing a student's state of interaction with one learning module, and each "sentence" capturing the interaction with the entire sequence. We used second order Markov chains to learn the patterns of this new "language," with each chain using the interaction states on two given modules to indicate the interaction states on the following two modules. By visualizing the Markov chains that lead to interaction states associated with either disengagement or high levels of engagement, we observed that: 1) disengagement occurs more frequently towards the end of the 10 module sequence; 2) interaction states associated with the highest level of learning effort rarely leads to disengaged states; and 3) states containing brief learning events frequently lead to disengaged states. One advantage of our approach is that it can be applied to log data with relatively small numbers of events, which is common for many online learning systems in college level STEM disciplines. Combining quality information with event logs is a simple attempt at incorporating students' internal condition into learning analytics.

Markov chains, online learning modules, log data analysis

1. INTRODUCTION

Understanding and predicting students' learning behavior by mining the log files of online and computerized learning systems has been the focus of a significant body of research in educational data mining. For example, many studies have modeled student learning as a chain of ordered events such as opening a page, viewing a video, or solving a problem [8, 9]. Events are often represented by a binary variable, e.g. whether the student accessed a webpage or answered a problem correctly [8, 14]. While describing events using binary variables can significantly reduce the complexity of the data, doing so can remove important

information from event logs. One indicator of the quality of an event is its duration. For example, abnormally short problem-solving attempts have been associated with either random guessing due to low test-taking effort [4] or answer copying [1]. In two earlier studies [6, 7], we demonstrated that learning events can be separated into "Brief" (B) and "Normal" (N) categories by applying a mixture model clustering algorithm using the time-on-task data alone, since other measurements such as the number of practice problems answered are highly correlated with time-on-task.

We combine duration-based categorical quality labels such as "Brief" or "Normal" with conventional binary event states, such as "Pass" or "Fail," to analyze the log data obtained from students' interaction with 10 Online Learning Modules (OLMs). OLMs are a form of online instructional design in which students progress through learning modules in a pre-determined order [5–7]. Students are required to attempt the assessment problems at least once before accessing the accompanying learning resources in each OLM. The restrictive structure of OLMs has major advantages for data analysis, providing more accurate estimations of duration information. Assessments and learning events are closely coupled on each module; the OLM structure itself improves the interpretability of log data events.

We combine the event logs with categorical quality labels to form a simple artificial language. Each event, such as "Brief Pass" or "Normal Fail," becomes part of a "word" that captures students' interaction with either the assessments or the learning components of a module. Four such "words" form a "phrase" that describes a student's state of interaction with one section of the OLM, and each 10 word "sentence" corresponds to a student's interaction with the entire OLM sequence. Can we gain insight into the patterns in students' learning behavior by understanding the underlying "grammar" of this artificial language? Are there certain combinations of words in these phrases that are frequently followed by other words which indicate that the student is either disengaged or highly engaged with the learning from the OLM sequence? We answer these questions by utilizing a second order Markov chain, a common technique used in natural language processing.

The Markov model can be trained using a relatively small number of events from a student population of approximately 250, owing to the increased information by introducing the quality labels. This advantage is critical for modeling student learning behavior for many STEM disciplines, where solving one problem can take 5 to 10 minutes. A typical weekly online homework assignment of 10 problems may only generate 30 to 50 major events. We demonstrate that it is possible to construct a Markov model using log data from 10 OLMs for a college physics class of approximately 250 students. The resulting Markov chains are visualized to reveal combinations of states that lead to states associated with either disengagement or high levels of engagement in following modules. Engagement is a

Matthew Guthrie and Zhongzhou Chen "Adding duration-based quality labels to learning events for improved description of students' online learning behavior" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 560 - 563

complex concept that has different definitions depending on context and measurement [2]. We adopt a pragmatic definition of engagement to indicate that students spent a normal or extended amount of time (and likely cognitive resources) on consecutive modules, emphasizing the cognitive and behavioral aspect of engagement, bearing similarity to the definitions proposed by Miller [11] and described by Motz, et al. [12].

2. MET ODS

2.1 Structure of OLM and OLM Data

Data analyzed in this study were collected from student interaction with 10 OLMs assigned as homework to be completed over a period of two weeks in a calculus-based college physics class. Students were not required to finish the entire sequence in one session, but the modules must be completed in the order given. As described in detail in several earlier papers [5–7], each OLM consists of an assessment component (AC) and an instructional component (IC). Students are required to attempt the AC at least once before being able to learn from the IC and can make additional attempts after interacting with the IC. Most interactions with each OLM can be divided into three stages: **Pre-Learning**: attempting the AC once or twice before accessing the IC, **Learning**: interacting with the IC after one or two initial failed AC attempts, and **Post-Learning**: making additional attempts on the AC after learning from the IC. If a student passes the AC during the Pre-Learning stage, they will not have the following two stages as the student will immediately proceed to the next OLM.

2.2 Combining Quality Labels with Events

For each Pre-Learning and Post-Learning stage, students' interaction with the AC is captured by the attempt outcomes: "Passing" (P) or "Failing" (F). The quality of each attempt is estimated from the duration of the attempt, t , which is classified into three categories: "Brief" (B: $t < 40$ s), "Normal" (N: $40 \text{ s} \leq t < 180$ s), and "Extensive" (E: $t \geq 180$ s). These cutoffs were determined based on a mixture-model clustering method applied to log-transformed attempt duration data [7]. Combining the quality categories with the attempt outcomes results in six different states: BF, BP, NF, NP, EF, and EP. The EF and EP states are only assigned to the Post-Learning stages, since there were significantly fewer attempts with $t \geq 180$ s in the Pre-Learning stages, and it was less clear whether those longer attempts resulted from longer problem-solving time or students leaving the system. Previous work explains these categories and cutoffs in detail [7].

For the Learning stage, students' interaction with the IC was modeled as a single learning event described by a binary variable. The duration of the learning event is classified as "Brief" or "Normal" according to cutoffs determined for each module by a mixture-model clustering analysis of learning time distribution [7]. An isolated "Brief" category does not necessarily imply that the event is of lower quality. Brief learning can result from a student having a high level of incoming knowledge and only needed to quickly view the learning resources to answer the problem. In a small number of cases, students made 3 or more failed attempts on the AC before accessing the IC or kept attempting the AC until all attempts were used up without accessing the IC. Those cases are classified as "Other." In even fewer cases, due to a corrupted log file or other system glitch, some students were able to proceed to the next module without finishing the current module. Those cases were classified as "NAOther," making a total of 28 possible states, listed in Table 1.

Table 1 All possible interaction states. D Disengaged. E Highly Engaged. See section 2.2 for other acronym definitions.

State	Rank	Indication	State	Rank	Indication
NAOther	0	D	BF-N-EP	14	E
Other	1	D	NP- -	15	E

BF-N-BP	10		NF-N-NF	24	E
BF-N-NF	11		NF-N-NP	25	E
BF-N-NP	12		NF-N-EF	26	E
BF-N-EF	13	E	NF-N-EP	27	E

2.3 Defining States Associated with Either Disengagement or High Engagement

It is difficult to estimate the level of engagement associated with a state, and the same state can be observed from students with different levels of engagement, though there are several states that are more likely to be associated with either a very low or a very high level of engagement with the learning process. For example, "Brief" learning events are more likely than "Normal" learning events to come from students who skimmed through the content [7]. Students displaying consecutive "Brief" events on the same module, such as in state BF-B-BF, are more likely to be disengaged with the learning process.

Consecutive "Normal" or "Extensive" events are more likely to come from students who are highly engaged with learning. While individual "Extensive" events may be caused by a student leaving the computer without exiting from the module, it is much less likely that three such events occur on the same module. We assumed that states with three consecutive "B" labels or BP- - are more likely associated with disengagement. BP- - is included because "Brief" problem solving occurs in under 40 s, which likely resulting from a guessing attempt, or answer copying event [7]. States with three consecutive "N" or "E" labels or NP- - are likely associated with higher engagement. We did not distinguish between productive and unproductive engagement; failed attempts are also included in high engagement states. There are two exceptions to these rules: First, the "Other" state is classified as "Disengaged," since most engaged students should at least look at the instructional resources after two failed attempts. Second, the BF-N-EF and BF-N-EP states are classified as highly engaged, since it is possible that the student quickly decided that the assessment problem was too difficult and immediately engaged in the learning process.

2.4 Training of the Markov Model

We define four sequential states to be a "phrase," a balance between model accuracy and available computational power. Phrases are analyzed in the context of the modules in which they occurred. Ten states are defined as a "sentence" and each student contributed a ten-state sentence to the text corpus. The Markovify Python library [10] was used to parse the text corpus. We utilized second order Markov chains because student interaction on a single module is unlikely to adequately indicate the complexity of their subsequent behavior. The Markov model was used to build second order Markov chains for every combination of initial states in modules 1 and 2, modules 6 and 7, and modules 7 and 8. The Markov chains

were used to investigate student behavior as they progressed through the modules and to infer how changes in behavior can be related to student engagement levels.

3. RESULTS

3.1 Outcomes of Second Order Markov Chain

For a given pair of states on the two input modules, we use the Markov model to return the probability of observing states in the two following modules. We consider a chain as “probable” if the probability of the last two states adds up to more than 100%. On average, 0.2% of all chains generated are considered probable. The three cases for which we ran the Markov model are listed in Table 2, along with the number of probable chains in each case. Those three cases are of particular interest because a previous analysis of the data [7] revealed that more students have lower levels of engagement in modules 3, 8, 9, and 10.

Table 2 Combinations of input states for modules (M1-M10) which were analyzed in this study.

Case	Input	Predict	All chains	Probable chains	Disengaged chains	ighly Engaged chains
I	M1 M2 M3 M4		55664	169	3	66
II	M6 M7 M8 M9		45472	65	18	15
III	M7 M8 M9 M10		72912	108	31	16

Figure 1 Probable chains that lead to consecutive disengaged states (red) or highly engaged states (blue). Darker lines indicate where multiple chains overlap blue and red zones highlight states associated with disengagement or high engagement, respectively.

Figure 1A (M1-M4) shows significantly more chains leading to highly engaged states on M3-M4 over disengaged states. On M1, those chains started from either a variety of states above NP- -, or from Other and NAOther. On M2, most of the chains concentrated on three states: 25: NF-N-NP, 15: NP- -, and 1: Other. While 25 and 15 were highly populated states in the original text corpus, state 1 was scarcely populated for M2; very few students were consistently disengaged on both M3 and M4, which appear early in the learning sequence and cover less difficult concepts. Figure 1B (M6-M9) shows there were almost an equal number of chains leading to either engagement or disengagement on M7 and M8. Most of the chains leading to disengagement passed through one of the states between 15 and 24 on M7. More than half of those chains started in states 2 and 3 on M6. Several chains leading to high engagement started with high effort states on M6 and passed through Other or NAOther on M7. Every chain (except one) starting from or passing through one of the top three states (25-27) led to high engagement, and every chain starting with disengaged states led to disengagement on M8 and M9. Figure 1C (M7-M10) shows there were more chains leading to disengagement over

3.2 Markov Chains Leading to Consecutive Disengaged or ighly Engaged States

We are interested in chains that could indicate engagement or disengagement with the learning process. We consider a student disengaged from the learning process if their interaction states are indicative of disengagement on the last two modules in a chain. If a student’s interaction states are associated with high engagement on the last two modules, the student is considered as highly engaged. The number of chains that lead to consecutive disengaged or highly engaged states on the last two modules are listed in Table 2. Other chains are not included in this analysis because the relation between engagement and the states on the last two modules were not as clear as the chains included. We plot all the chains indicating disengagement or high engagement for each of the three cases in Figure 1. In each case, the 28 interaction states are arranged according to the order listed in Table 1.

This ordering groups states according to similarities in Pre-learning, Learning, and Post-Learning stages, listed from low to high in the order of “B,” “N,” and “E” in quality labels. States with passing events are assumed to be of higher engagement than those with failing events. States associated with disengagement are placed at the bottom and states associated with high engagement are placed at the top, except for states 13-15 in Table 1. For states near the middle of the pack, the ranking does not reflect the learning effort required for each state, as it is difficult to estimate the level of effort required by 11: BF-N-NP compared to 19: NF-B-NP.

engagement on M9 and M10. The chains leading to disengagement started at a variety of states on M7, and forms two groups on M8. The first group passes through disengagement between states 0 and 4, and the second group passes through states between 15-21. Most of the high engagement chains either started from state 26 on M7 or passed through state 27 on M8.

4. DISCUSSION

By comparing Figure 1A-C we identify four common patterns. **1. Disengagement happens late** chains leading to disengagement occur much more frequently on later modules in the sequence. This type of behavior is expected since the difficulty of the modules increase towards the end, yet each module is worth the same amount of course credit. Therefore, students had less incentive to devote effort on the harder modules. **2. Disengagement-free states** states 25-28 are seemingly “immune” to chains leading to disengagement. In all three cases, only two of those chains pass through these states, while most of the chains leading to high engagement involve those states on at least one input module. Students who spend an extensive amount of effort on one module

are more likely to be more persistent, especially on difficult modules towards the end. **3. Disengagement hot zone** states 15-24 (the white area between two blue bands in Figure 1) seem to be a “hot zone” for chains leading to disengagement in all three cases, especially when the state appeared on the second module in the sequence. Those states have a “Brief” label on either the learning stage or the post-learning stage. A brief event in the learning and post learning stages could indicate subsequent disengagement behavior more effectively than a brief event in the pre-learning stage. **4. -shaped high engagement chains** several chains leading to high engagement started with states beyond 15 and passed through either Other or NAOther on the second module, forming a V-shape on Figure 1C. Even highly engaged students may occasionally display disengaged states on certain modules. It also may suggest that the two “other” states are not always associated with disengagement as previously thought. These patterns can be valuable for development of an intelligent and personalized learning system that recommends different learning resources to appropriate student populations [13]. The patterns can also help instructors prioritize efforts in improving the OLMs.

There are several caveats to be investigated and addressed in future studies. Only three pairs of modules were analyzed. Whether the patterns observed are general to all modules or specific to the selected cases can be answered by analyzing every pair of input modules. We adopted a narrow definition of engagement; students spent an expected or extended amount of time completing each component in a single module. This definition is appropriate for the purposes of the current study, but the relation between time-on-task and engagement should be investigated. The current Markov model “predicts” student behavior based on their interaction states in preceding modules, but students’ decisions to engage or disengage from learning involves complex metacognitive processes influenced by multiple external factors (knowledge, instructional condition, metacognitive skills, and emotional states) [3]. We can achieve more accurate outcomes by including more factors that influence students’ metacognitive processes. This study utilizes simple labels obtained from clustering algorithms on time-on-task data. Future studies should investigate the validity of those labels, and to find new and better-quality indicators for the existing events and new events in other learning systems.

We relied on the restrictive structure of OLMs, providing a regular and simple data structure and allowing for straightforward interpretation of interaction states. Events and quality labels used to generate the artificial language can be obtained from essentially any online learning platform, and more sophisticated Markov models are capable of learning languages with many more irregularities. An extension of this work will be to investigate how the current method can be modified and applied to more common learning systems that are more accessible to the average instructor.

5. ACKNOWLEDGMENTS

We thank the Learning Science and Technology team at the University of Central Florida led by Dr. Francisca Yonekura for developing the Obojobo platform and providing technical support.

ABSTRACT

Discussion forums can be a rich source to analyze students' questions but it can be challenging to find relevant categories of questions. We considered here students' posts from the discussion forum of four editions of a same French MOOC on Project Management. We extended a coding scheme to annotate questions based on their content (course vs. non course) and trained 3 stages of an automatic annotation model. Then we studied the correlation between the nature of the questions asked and students' performance and self-regulation. The results are promising and reveal, for the minority of students active on forums, the possibility to use this feature to better estimate their performance and some of their self-regulation skills based on questions they ask.

Keywords

Student's question, discussion forum, coding scheme, self-regulation, student's performance, MOOC

1. INTRODUCTION

Students' questions play an important role in the learning process and are meaningful for both learning and teaching science [4]. The need for students to ask questions, or to point out errors in the course, are as salient in distance e-learning as they are in a classroom setting, thus emphasizing the importance of discussion forums in online learning and in MOOCs in particular [1]. Forums are not only a place for socialization, but also a place where learning happens, as learners post questions, opinions, and concerns, which are viewed, rated and answered by fellow learners and/or teaching staff. Therefore, we conducted analyses to explore the

nature of questions asked by students in a MOOC forum and particularly tried to see the relationship between those questions and students' performance and self-regulation skills. More particularly, we wanted to answer to the following research questions:

(RQ1) Is it possible to reliably annotate questions extracted from MOOC forum posts according to a fine-grained multi-level coding scheme?

(RQ2) Is there a relationship between the nature of the questions asked on a MOOC and the students' performance and mastery of self-regulated skills?

2. STATE OF THE ART

Studying discussion in MOOC forums is still an ongoing topic of research. Zeng et al. [11] identified the confusion messages by using discussion forum posts derived from large open online courses. Sentiment analysis of MOOC forums discussions can also help in identifying the dropout behavior from students' posts [10].

Researchers have studied students' questions in a variety of educational settings, such as classroom [3], tutoring [7] and online learning environments [9]. Graesser and Person [7] developed a taxonomy of questions asked during tutoring sessions to be used for automatic question generation. Although their taxonomy could be relevant to our work, some categories included high quality 'deep-reasoning questions' and are associated to patterns of reasoning which are difficult to identify automatically.

We also investigated how self-regulated learning (SRL) was used to analyze students' interactions in online environments. Dettori et Persico [6] used a taxonomy of indicators of SRL to analyze directly what kind of students are self-regulated from their messages. Bouchet et al. [2] characterized students via clustering according to their interactions with an intelligent tutoring system fostering SRL.

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 564 - 567

Table 1: Descriptive statistics of the 4 MOOC sessions considered (registration, messages and success)

Session	GDP5	GDP6	GDP7	GDP8
Students reg.	17579	23315	19392	24603
Answered to quiz 1	4842	7537	5951	7998
Bas. certif. obtained	2282	3900	2393	4526
Adv. certif. obtained	503	697	559	589
Nb of posts	7655	10597	12224	14072
Nb of unique posters	2087	4717	3504	4760

3. CONTEXT AND DATASET

We consider in this paper four datasets made of forum messages posted in four different sessions (5 to 8) of the same biyearly French MOOC on project management called GDP (French acronym for project management) held in 2015 and 2016. The MOOC allows participants to obtain a basic certificate (15-25 hours estimated workload), and an advanced one (35-45 hours). Therefore for each participant we can determine two final grades and whether one, both or none of the certificates were obtained. The forum is organized around threads created by the pedagogical team to answer to technical or administrative issues, about homework or course content, *etc.* Table 1 provides some basic statistics on the forum usage and number of students registered.

Additionally, participants to the MOOC are invited to fill an optional (only 0.25% bonus points for filling it) research questionnaire after 2 weeks in the MOOC which included 21 psychometrically evaluated questions evaluating their SRL skills in an online setting [5] using 7-point Likert scales along 4 dimensions: (1) cognitive and metacognitive strategies, (2) procrastination, (3) context adaptation, and (4) peer support. We filtered out the participants who failed to answer to embedded attention check questions (*e.g.* "answer 5 here") to increase the reliability of the data considered.

4. QUESTION CODING SCHEME

To identify the nature of students questions in the forums, we considered a sample of 500 messages from the 4 sessions, randomly divided into 3 sub-samples (200/100/200). We applied 4 categorization steps to define a coding scheme as proposed in another context by Harrak et al. [8].

The raw corpus contains unstructured and noisy messages from students (*e.g.* a message can contain several questions, opinions, answers to issues not course related, *etc.*). We first filtered out the messages from the instructors, those that are a reply to other ones (*i.e.* not the root messages) and the explicitly non-course related topics (*e.g.* thread dedicated to technical issues). The messages were then segmented into several questions (using Python library NLTK) and annotated according to their content. The course-based questions were annotated with the coding scheme from [8] (summarized in upper Table 2) which consists in 4 independent dimensions: a mandatory main one (dimension 1), and 3 optional ones (dimensions 2 to 4). For instance, a question could be a request to re-explain the way something work by providing another example (tagged as Ree on dimension 1, Exa on dimension 2, Man on dimension 3, and nothing on dimension 4, *i.e.* vector [Ree,Exa,Man,0]). The non-course related questions were then annotated according to newly

Table 2: Coding scheme for course-based students' questions (Dim 1 to 4, adjusted from [8]) and for non-course related questions (Dim0)

Code	Question category	Description
Dim1-4: Course-based questions		
Dim1: question type		
Ree	Re-explain / redefine	Ask for an explanation already done in the course material
Dee	Deepen a concept	Broaden a knowledge, clarify an ambiguity or request for a better understanding
Ver	Validation / verification	Verify or validate a formulated hypothesis
Dim2: explanation modality / question subject		
Exa	Example	Example application (course/exercise)
Sch	Schema	Schema application or an explanation about it
Cor	Correction	Correction of an exercise in course/exam
Dim3: explanation type		
Def	Define	Define a concept or term
Man	Manner (how?)	The manner how to proceed
Rea	Reason (why?)	Ask for the reason
Rol	Roles (utility?)	What's the use/function
Lin	Link between concepts	Verify a link between two concepts, define it
Dim4: verification type		
Mis	Mistake / contradiction	Found potential error in course/teacher's explanation
Kno	Knowledge in course	Verify knowledge
Exp	Expected knowledge	Verify expected information in exam or quiz (assessment)
Dim0: Non-course related questions		
Soc	Socialization	Social questions
Adm	Administrative issues	MOOC administration: registration, certificate, <i>etc.</i>
Exa	Exam/ quiz	Ask for assessment modality: notes, format, <i>etc.</i>
Tec	Technical issues	Detect a technical problem and ask for solution
Res	Ressources not found	Ask for not found ressources
Too	Tools	Ask for tools for a task
Pha	Phatic	Question that has no real value or information

defined dimension 0 (*cf.* lower Table 2). Two human annotators made separate independent annotations on each dimension, and their agreement was evaluated using Cohen's Kappa. First the kappa was calculated for the agreement on whether a segment was a question or not ($\kappa = 0.85$) and then on explicit questions only ($\kappa = 0.96$). Then agreement was calculated for the topic of the question (course *vs.* non-course, $\kappa = 0.85$). Finally, kappas were calculated for dim1 to 4 ($\kappa_1 = 0.70$, $\kappa_2 = 0.61$, $\kappa_3 = 0.69$, $\kappa_4 = 0.57$) for course questions and for dim0 for non-course questions ($\kappa = 0.58$).

5. AUTOMATIC ANNOTATION

To annotate the set of questions asked by the students, a semi-automatic tool based on rules and keywords manually weighted was used in prior work to annotate automatically the questions. Although effective (average kappa of 0.70), many questions were not annotated by this tool [8], which led us to develop another automatic tool using machine learning techniques trained on the corpus of questions.

Table 3: Kappa values between automatic annotation and the reference manual annotation

Classifier	SVM	DT	GLM	GBT	K-NN	NB	RI
(1)	0.60	0.91	0.91	0.91	0.80	0.54	0.91
(2)	0.66	0.40	0.62	0.51	0.33	0.47	0.43
(3)	-	0.28	0.35	0.37	0.22	0.21	0.11
(4)	-	0.61	0.63	0.68	0.27	0.07	0
(5)	-	0.30	0.09	0.39	0.05	0.03	0.37
(6)	-	0.50	0.56	0.54	0.14	0	0.26
(7)	-	0.48	0.45	0.47	0.19	0.07	0.35

(-): Not suitable for non binary data

We performed the classical preprocessing steps on the training sample of 1307 segments (500 messages) manually annotated: tokenization, stemming, punctuation removal (except for '?') and stopwords (non-meaningful words) removal. We then extracted all the unigrams and bigrams and counted their occurrences in that sample. Each of the 1307 segments was represented by a binary word vector ('1' if the word is in the segment, '0' otherwise). We finally reduced the number of keywords extracted (high number of keywords compared to the number of segments) to keep the most important and significant ones using a feature selection technique (removing less frequent and correlated unigrams/bigrams).

We designed a 3-stage annotator to identify segments with questions, course *vs.* non-course related questions and the nature of those questions. Overall, 7 classifiers were trained to annotate a segment respectively: (1) into question/non-question; (2) into course/non-course related questions; (3) for non-course related questions, according to dim 0; (4-7) for course-based questions, according to dim 1 to 4. For each classifier we trained models using different machine learning techniques with a 10-fold cross-validation: Support Vector Machine (SVM), Generalized Linear Model (GLM), Gradient Boosted Trees (GBT), Decision Tree (DT), K-NN, Naive Bayes (NB) and Rule Induction (RI), each with various values of hyperparameters. For each classifier, the input was the words vectors representing the segments in terms of keywords, and the label to predict was the value associated to the segment in that dimension. Classifiers (1) and (2) took a binary values and each of the other classifiers took nominal values (varying from 3 to 7, according to the dimension).

We then calculated the Kappa values between the predictions from the classification models and the ground truth values from the manual annotation (*cf.* Table 3). The entire corpus of segments of messages was annotated by the techniques with the highest performance for each classification.

6. RELATIONSHIP BETWEEN QUESTIONS, SUCCESS AND SELF-REGULATION

6.1 Data coding

To study the relationship between question type and success and self-regulation, we coded for GDP8 students who posted on the forum the number of segments categorized as :

- an explicit question (NbQ)
- not a question or an implicit one (NbNQ)
- a non-course question (NbQ-NC)
- a non-course question corresponding to a socialization (NbQ-NC-Soc), an administrative issue (NbQNC-Adm), an exam

- (NbQ-NC-Exa), a technical issue (NbQ-NC-Tec), a resource not found (NbQ-NC-Res), a tool issue (NbQ-NC-Too) or a phatic (NbQ-NC-Pha),
- a course question (NbQ-C),
- a course question about a reexplanation (NbQ-C1-Ree), a request to go deeper in a concept (NbQ-C1-Dee), or a verification (NbQ-C1-Ver)
- a course question requesting an example (NbQ-C2-Exa), a schema (NbQ-C2-Sch), or a correction (NbQ-C2-Cor),
- a course question asking for a definition (NbQ-C3-Def), the way to proceed (NbQ-C3-Man), the reason for something (NbQ-C3-Rea), the role of something (NbQ-C3-Rol), or the link between two concepts (NbQ-C3-Lin),
- a course question asking for a verification regarding an apparent mistake (NbQ-C4-Mis), knowledge from the course (NbQ-C4-Kno) or whether something is expected to be learned or not for the assessment (NbQ-C4-Exp).

In addition to those variables relative to the questions asked, we also have for each student :

- **four SRL scores**, measured by a questionnaire [5]. Although the authors average the 4 individual scores into an overall SRL score (with procrastination coded in a reverse manner), we believed they captured different facets of SRL which could individually be associated to different question asking behavior. Therefore we defined for each student their lack of procrastination score (Sc_{ONPr}), their context score (Sc_{Ctxt}), their strategy score (Sc_{OStr}) and their peer support score (Sc_{OPee}). Each score is an average of 5 to 6 questions, between 1 and 7,
- **two performance scores** for the basic/advanced MOOC track (Sc_{Bas} and Sc_{Adv}), a value between 0 and 100.

6.2 Correlation analysis

Method: We calculated for each question variable (NbQ-*) its Pearson correlation coefficient (r) with each of the self-regulation and performance variables (Sc_{*}).

Results: 286 students posted at least one message with a segment containing an explicit question. The results (not all detailed here) reveal that asking explicit questions (on the basic [$p = .012, r = .148$] and the advanced tracks [$p = .000, r = .237$]), and questions on a topic relevant to the course (on the basic [$p = .010, r = .153$] and the advanced tracks [$p = .000, r = .253$]), is a behavior positively correlated with the performance. The questions the most strongly positively correlated to performance are the ones to check one's understanding (Ver) regarding a theme of the course ($p = .000, r = .292$) or a skill one is expected to master for the final exam ($p = .000, r = .282$).

123 students among those who posted at least one message with an explicit question had also filled the SRL questionnaire. The results (summarized in Table 4) reveal that procrastination is not correlated with any particular type of question. It is however logically negatively correlated with the score in the basic ($r = -.349$) and advanced ($r = -.372$) tracks of the MOOC, *i.e.* students who procrastinate have lower scores overall. The context facet of SRL is positively correlated only with the number of messages not containing a question (NQ). The two other facets are more interesting, as the students who self-report being good at using cognitive and metacognitive strategies (such as note-taking) while

n/a: no segment annotated with this code

Table 4: Correlation between the question types and the four SRL scores

learning online are asking less question about the organization of the final exam, less phatic questions and less verification questions. Thus it seems that being more organized, maybe when they watch the video or go through pages of contents, they have a lesser need to verify information probably already mentioned somewhere. As for students who self-report being good at interacting with others to learn in a more efficient manner, logically they post more messages (both questions and non-question), which can be related to the course or not. When analyzing the nature of the questions they ask, they socialize more with others and ask more administrative questions. They also tend to ask very practical questions about the course about how to perform a task or the reason some concept is working that way.

7. DISCUSSION AND CONCLUSION

We have shown it is possible to annotate not only messages from a MOOC forums, but individual questions within sometimes long messages. Segmenting messages allows to distinguish finer-grain intent of the student, using an adapted coding scheme for both course and non-course related questions. This result opens the way to automatically tagging MOOC posts, for instance to help the pedagogical team to quickly know the intent of the messages that have not received a reply yet. Another interesting aspect is the fact that the nature of the questions asked within the messages provides information on some aspects of students' level of self-regulation (their tendency to interact with others for learning and their use of cognitive and metacognitive strategies). It is also worth noting that some of the patterns found here, such as the fact that students who ask verification questions tend to succeed overall better than others, are consistent with previous results in a different context [8].

Some limits include: the topic of the MOOC which hindered the classifiers performance with its low technical vocabulary (words overlap between the content and context of the course) and the average kappa values obtained for the classifiers which can reduce the impact of some correlations observed, correlation values which are themselves never extremely high even when $p < .05$. Finally, as always with results relative to MOOCs forum, they are only used by a minority of active learners. Future directions involve considering some messages excluded here (messages that are not root in the thread, technical or socialization threads which could fit in the non-course coding scheme), and considering forums from MOOCs on different themes to build up a larger corpus of messages, to try to improve the annotator performance.

ABSTRACT

To address the changing landscape in educational assessment, the National Assessment of Educational Progress (NAEP) transitions to digitally-based assessments (DBAs). DBAs permit the collection of data about how students progress through assessments, which was not feasible with paper-based assessments. The exploration of process data is a relatively new field, with most current studies focusing on response time analyses. This study will incorporate other process data information, such as the frequencies and durations of support functions used related to students' cognitive processes. Using data from one released block of the NAEP 2017 Mathematics Assessment for Grade 8, this study aims to provide an understanding of how students' use of support functions (e.g. drawing and highlighting) are related to response time (RT) and mathematics achievement.

Keywords

Process data, Digitally-based assessments, NAEP, Support functions.

1. INTRODUCTION

The study of response processes was explicitly stated as one source of validity evidence in the 2014 Standards for Educational and Psychological Testing [1]. Response processes are the actions or thought processes that test takers demonstrate when engaging with assessments. Think-aloud protocols, interview sessions, eye-tracking technology, and response time procedures are all common ways of capturing such processes. Since the advent of large-scale, digitally-based assessments (DBAs), the recording of item response time (RT) has resulted in an increased number of research studies investigating a wide range of topics, such as the development of psychometric models [7, 8], modeling of response speed and accuracy [3], student motivation [11], and the relationship between response time and item- and person-level factors [6].

Yet, exploration of specific functions and their relationship with

item response time (RT) has been sparse. With the availability of process data, students' use of support functions such as drawing, and highlighting have also been recorded. The collection of this ancillary data in modern assessments can lead to potential advances in the type of research normally reserved for assessment data. To our knowledge, there has not been a study focusing on use of support functions, in the context of a digitally-based mathematics assessment. However, literature in other contexts (e.g. classroom assessments for reading and science subjects) has highlighted the connection between students' support-related cognitive processes and better learning outcomes [2, 4, 9]. Undergirded by the cognitive theory of multimedia learning [7], the effectiveness of drawing (i.e. learner-generated representation of provided material) was confirmed [10]. Similarly, students' navigation behavior (i.e. selection of task-relevant hypertext pages) was found to be the key to understanding the variation in student comprehension of digital texts [4], while students' highlighting behavior was found to play a role in encoding and organizing information [5].

For the current study, response processes are defined as the actions that students demonstrate, using available digital tools when responding to test items on NAEP. NAEP is the largest nationally representative assessment of what America's students know and can do in various subject areas. NAEP is administered to 4th, 8th, and 12th grade students, every two years in various subjects. Specifically, the following research questions will be examined in the present study:

- 1) How often do students display support functions in the NAEP mathematics assessment? How do support functions differ by item type?
- 2) What is the relationship between support functions and RT?
- 3) Can distinct groups of students with unique patterns of support functions be identified?
- 4) Do clusters, (i.e., identified groups), have a relationship with any prominent observed variables?
 - a. What is the prevalence of male and female students in these clusters?
 - b. What is the prevalence of different race/ethnicity groups in these clusters?
 - c. What is the prevalence of different ELL and IEP status in these clusters?

- d. Is there a difference in mathematics performance between clusters?

2. METHODS

2.1 Data

The current study used a single block of items (i.e., Block MC) that was recently released from the NAEP 2017 Grade 8 Mathematics assessment. The block included 25,300 8th grade students. The sample was selected using a two-stage, stratified random-sampling design, with schools selected in the first stage, and students selected in the second stage. The assessment was administered to students using a balanced-incomplete-block spiraling design, in which test booklets for each student contained two of 15 blocks of cognitive items. The maximum amount of time students could spend on each block was 30 minutes. Students with extended time accommodations and interrupted sessions were excluded during the data cleaning process in the current study.

The focused block comprised six item types and a total of 15 items: a) two multiple-choice (MC) items, b) three composite constructed response (Composite CR) items, c) two multiple-selection (MS) grid items, d) five matching items, e) one zone item, and f) two fill-in-the-blank items. Each item produced student actions captured in the process data. There were nearly 13 million instances of actions produced from 37 unique functions (e.g. drawing, highlighting, and navigating).

2.2 Analysis

To examine the relationship between support functions, item response time (RT), and mathematics achievement, a preliminary list of support functions was created based on data collected in NAEP 2017 Grade 8 Mathematics process data. After a descriptive exploration, 12 out of 37 functions were selected to be included in the study (Table 1). Student response time per item was calculated, and results were aggregated to get the total response time for each student. The relationships were explored for all support functions and time usage via descriptive methods.

To identify heterogeneous use of support functions in preliminary

analyses, students were clustered based on their use of support functions via a model-based clustering approach that identifies heterogeneity in the population based on the observed data (e.g., Everitt, 2005), using the EM algorithm for maximum likelihood estimation. Subpopulations were modeled separately, and the overall population was modeled as a weighted sum of those subpopulations using finite mixture models. NAEP scale scores for each examinee are reported as a set of 20 plausible values (PVs) that represent a distribution of possible scores and apply to students from measured population groups. Instead of individual student scores, plausible values describe the situation where true scale scores describing the underlying performance for each student are unknown. To examine student performance, we used plausible values (PVs) at the theta scale as predicted ability based on the performance across two blocks (instead of per block).

3. Results

3.1 Support Functions in NAEP Mathematics

To address RQ1, we explored how often students displayed support functions in the NAEP grade 8 mathematics assessment. Frequencies of the actions were calculated overall and per item type. The overall frequencies for the 12 support functions are presented in Table 1, together with the percentage of students who used the support function at least once.

Table 1 shows that students displayed varied use of support functions. For example, functions related to screen orientation, such as vertical item scroll and focusing were used at least once by almost all students. The navigation function was used by 75% of students, while functions like draw and highlight were used much less often by 52% and 19% of students, respectively.

However, some of the support functions were expected to be used more frequently for specific types of items. Therefore, the percentage of students that used each function at least once per item type was also examined (see Figure 1).

As expected, Figure 1 shows that some of the functions were only available (or used) for specific item types. For example, Focus (i.e., Receive Focus and Lose Focus) was only activated for composite constructed response and fill-in-the blank items, as this

Table 1. Frequency Use of Support Functions

Support Function	Description	Frequency	Percent of Students Used Function at Least Once
Draw	Student finished drawing with the scratchwork draw tool	900597	52
Vertical Item Scroll	Student scrolls an item which has a vertical scrollbar	557856	99
Receive Focus	When a response entry field in a discrete item receives focus	521631	99
Lose Focus	When a response entry field in a discrete item loses focus	509976	99
Click Progress Navigator	When the Student selects a tab in the Progress Navigator for discrete items	191521	76
TextToSpeech	Recorded when the student turns test to speech/read aloud more on or off	161829	30
Erase	When the Student finishes erasing with the Scratchwork Erase tool	88205	33
Equation Editor Button	When the Student selects a button in the Equation Editor tool	83993	38
Highlight	When the Student finishes highlighting with the Scratchwork Highlight tool	58972	19
Clear Scratchwork	When the Student selects the Clear Scratchwork button of the Scratchwork tool	37723	34
Open Equation Editor	When the Student selects the Equation Editor button to toggle the Equation Editor tool on	20669	40
Horizontal Item Scroll	Recorded when the Student scrolls an item which has a horizontal scrollbar	3414	3

function was associated with text entry.

Figure 1. Percentage of Students Using Support Functions by Item Type.

Similarly, equation editor was used for the same types of items but by much fewer students (15% for CompositeCR and 31% for Fill-In-Blank). The difference between Open Equation Editor and Equation Editor Button showed that some of the students opened the editor but did not click on anything in the editor for GridMS items. Figure 1 also shows that students used the navigation function the most on constructed response items. These items were probably more difficult or required more input from students, which is why students used navigation more on these items.

Although Draw and Highlight were used by less students, for those that did use the tools, results showed that they were used across all item types. To understand the use of the Draw tool, this finding will be connected with how much time students spent on this support function. For all other functions, some variation was observed in the percent use of support functions by item types, signaling that students may be using the support function features in different ways.

3.2 Support Functions and Total RT

To address RQ2, we explored the relationship between support functions and total response time (RT). We first calculated the frequency of the use of the support functions for each individual student by item. A summary of the frequency of each support function is presented in Table 2. For total RT, we summed the time spent across all items.

Table 2. Distribution of Support Function Frequency Use

Interpretation	1 st Q.	Mdn	Mean	3 rd Q.	Max	SD
Draw	0	#	35.6	50	1290	63.7
Vertical Item Scroll	10	20	22.1	30	200	15.6
Receive Focus	10	20	20.6	30	190	12.4
Lose Focus	10	20	20.2	20	190	11.8
Click Progress Navigator	#	#	7.6	10	100	8.9
TextToSpeech	0	0	6.4	#	570	21.8
Erase	0	0	3.5	#	490	10.7
Equation Editor Button	0	0	3.3	#	850	13.1
Highlight	0	0	2.3	0	350	9.8
Clear Scratchwork	0	0	1.5	#	140	3.9
Open Equation Editor	0	0	0.8	#	20	1.3

Horizontal Item Scroll	0	0	0.1	0	240	2.5
# Rounds to zero.						

As noted in Table 2, not all students used the support function tools. Therefore, the minimum number of the action frequency is zero for all functions. Table 2 further shows that individual students vary with the use of support functions.

Next, we explored the relationship between the use of support functions and total response time. As an example, we selected the drawing function (which was used by half of the students) and we explored the total response time between two groups of students: a) those that did not use the drawing tool and b) those that used the drawing tool. Figure 2 shows that after 22nd minute, there were more students who used the drawing tool than those who did not. A similar result was found for the highlight function. These results suggest that on the latter portion of the block, there are more students who use these tools, possibly because of a higher concentration of difficult items where support functions would be useful.

Figure 2. Total Response Time Used by Student Groups: Used or Not Used Drawing Tool.

3.3 Clustering Support Function Behavior

To address RQ3, we also explored if it was plausible to cluster students based on their support function behaviors (i.e., frequency). For this purpose, we standardized all support function frequencies (if students did not use a function at all, they have value of zero). We used only 10 of the support functions for clustering (we excluded Lose Focus and Open Equation Editor as they have almost the same function as Receive Focus and Equation Editor Button, respectively).

Our preliminary exploration led to a 3-profile solution via a model-based clustering algorithm. Figure 3 shows the clustering results for all students. The first extracted profile was represented by hardly any use of support functions. The second extracted profile was a composition of Receive Focus, Equation Editor Button, and Vertical Item Scroll, which provided evidence of students' monitoring processes operationalized by navigating [4] and modifying equations. The third extracted profile was a composition of Highlight, Draw, Erase, and Clear Scratchwork, which provided evidence of students' cognitive processes where they construct mental representations of the test content [7,10]. These results suggest that students' use of support functions can be classified into meaningful profiles, which are potentially related to different aspects of cognitive processes.

Figure 3. Profiles of Student Support Functions.

To address RQ4, we examined the profiles to see if they had a relationship with any prominent observed variables such as gender, race/ethnicity, ELL, and IEP status. Profiles were also examined to see if there were any performance differences.

For all observed variables and performance, there were no substantial differences between profiles, except in the case of gender, where there were more female students in profile one (no support function use) compared to male students.

Table 3. Distribution of Demographics by Profile

Profile	Profile 1	Profile 2	Profile 3
Gender			
Male (%)	34	56	50
Female (%)	66	44	50
Race/Ethnicity			
>1 Race, not Hispanic (%)	3	‡	‡
African American, not His (%)	16	17	16
Amer Ind/Alsk Nat (%)	2	‡	‡
Asian, not Hispanic (%)	5	‡	5
Hispanic of any race (%)	22	21	20
Native Ha/ Pac Island (%)	1	‡	‡
White, not Hispanic (%)	52	51	53
ELL			
No (%)	94	94	94
Yes (%)	4	‡	‡
Formerly ELL (%)	1	‡	‡
Performance			
Mean PV	-0.002	-0.001	0.050
Median PV	-0.024	-0.016	0.030

‡ Reporting standard are not met (too few cases).

4. CONCLUSIONS

Process data helps us to extract more information about how students interact with available digital tools when responding to

test items in digitally-based assessments. By exploring process student support functions, this study helps a variety of stakeholders, understand student cognitive processes when taking mathematics assessments. This would allow researchers to better understand the actual use of support functions by certain groups of students (e.g., those performing at the below basic level). Interestingly, the majority of students did not use the available support functions, which may be due to unfamiliarity with technology and could lead to a cold start (where students did not have enough information and time to learn the system tools). In all, process data on student support functions is an under-researched area with promise, and our study attempts to fill the research gaps in this field.

ABSTRACT

In this paper we investigate writing style development among Danish high school students. More than 10K students with more than 130K essays are analyzed. Writing style itself is often studied in the natural language processing community, but usually with the goal of verifying authorship, assessing quality or popularity, etc.

In this work, we analyze writing style changes over time, with the goal of detecting global development trends among students, and identifying at-risk students. We train a Siamese neural network to compute the similarity between two texts. Using this similarity measure, a student's recent essays are compared to their first essays, and a writing style development profile is constructed. We cluster these student profiles and analyze the resulting clusters. We evaluate clusters with respect to writing style quality indicators, and identify optimal clusters, showing significant improvement in writing style, while also observing suboptimal clusters, exhibiting periods of limited development and even setbacks.

Furthermore, we identify general development trends between students, showing that as students progress through high school, their writing styles deviate, leaving students less similar when they finish high school, than when they start.

Student clustering, Writing style analysis, Siamese Neural Network, Educational Systems

1. INTRODUCTION

One of the most essential skills, learned during the course of primary, secondary and high school, is writing. While the main focus of primary school are on basic writing skills, high school will be more focused on improving *the linguistic writing style* of a student, i.e. the quality of the written text as perceived by the reader. While the definition of quality in linguistic writing style is discussed [7], several measures are correlated to writing style being perceived as good, for instance use of vocabulary, sentence structure and readability

[5]. Our main focus is writing style *development* through the course of high school, while writing style quality will have a secondary role. We consider data from Danish high schools, consisting of Danish essays, and investigate the general development patterns among the students during the three years of study. The data is supplied by MaCom¹, the company behind the learning management system Lectio, used by 90% of Danish high schools. We identify patterns among thousands of students across different classes and institutions, allowing us to provide teachers with new insights, which the data available to the teacher might not show.

Our method allows for identifying students with deviating writing style development, or sudden significant changes in writing style, which could indicate cheating. Furthermore, we compute several *text quality* measures for the different development profiles, in order to determine whether a profile indicates improvement. Our approach is based on methods from authorship verification; we use a Siamese neural network for learning a writing style similarity measure. Using this measure, we generate and cluster writing style development profiles. The found clusters are then analyzed, in order to determine optimal and suboptimal development patterns. Our analysis of the MaCom data shows, how writing style changes during high school, supporting conclusions from the literature. [1, 2, 9]. While this paper presents a case study of the data from MaCom, the methods used for analysis are of independent interest, and not specific to the Danish language or high school.

Writing style analysis, has been studied in the natural language community for many years. Typically, the analysis of writing style is used as a middle link for tasks such as *authorship verification* [6, 8, 9], in which the claimed author of a text must be verified based on available previous work by said author. Some studies investigate the quality of writing, for instance prediction of popularity of news articles [10], or the quality of scientific articles [3]. Few studies consider development of writing style as the main objective, e.g. [1] which considers the change of writing style of two famous Turkish writers. Finally, several studies related to writing style have been conducted using the data available from MaCom. [2] investigates temporal aspects of authorship attribution while [9] applies neural network based authorship verification methods to the data.

2. METHODS AND SETUP

We describe in this section our method for tracking writing style development among students over time. Below, \mathcal{A} denotes the set of students, $\alpha \in \mathcal{A}$ denote a single student with texts $t \in T_\alpha$, while $T = \cup_{\alpha \in \mathcal{A}} T_\alpha$ denotes the entire corpus of texts. As we wish to compare writing style between different essays, we need a writing style similarity measure $s : T \times T \rightarrow [0, 1]$, which will be further utilized in the analysis. Primarily, we focus on determining development patterns by generating a *writing style development profile* P_α for each student α . These profiles are then clustered and analyzed with respect to different measures for text quality. Finally, we also explore how the similarity between random students change depending on their current progress through high school. This is done by sampling random pairs of texts $t_1 \in T_\alpha, t_2 \in T_\beta$ and computing their similarity. We then consider how the similarity changes depending on if α and β are in the same grade or not.

We utilize a Siamese neural network for computing the similarity $s(t_1, t_2)$ between two texts t_1 and t_2 . We considered several different architectures, using different input channels (e.g. char, word, part of speech tags), testing each option using a validation set. The optimal architecture was found to be the same as used in [9], which was evaluated on the same data set. The architecture uses only character level input. The texts are first encoded in the *encoding part* of the network, consisting of a character embedding (dimension 5), followed by two parallel convolutions (kernel size 4 and 8 with 500 and 700 filters respectively) and global max pooling layers, producing an encoding of size 1200. Encodings for t_1 and t_2 are then passed to the *decider part* of the network, which first computes the absolute difference between the encodings, before applying four 500 neuron dense layers using the ReLU activation function and a dropout rate of 0.3. Finally, a softmax layer with two neurons produces the final output.

The writing style profile P_α for student α is then computed by first determining their initial writing style. This is done by considering the early work of a student, consisting of the first m essays. P_α then consists of a chronologically ordered sequence of similarities, between any $t \in T_\alpha$ and these m essays:

$$p_i = \frac{1}{m} \sum_{j=1}^m s(t_i, t_j),$$

where t_i denotes the i 'th text handed in by the student. Note, that p_1, p_2, \dots, p_m are not independent, and thus we exclude the first $m - 1$ texts, and re-index such that $p_j = p_{i-m+1}$. Furthermore, for each text, we let τ_j denote the time in months since t_m was written, i.e. the time since p_0 , with $\tau_0 = 0$. Now, the final profile becomes the sequence consisting of pairs (τ_j, p_j) of length $|T_\alpha| - m + 1$.

These profiles are now clustered using a slightly modified k -means clustering. Before clustering, for each profile P_α , an approximate profile \hat{P}_α is constructed by interpolating values between any two consecutive pairs (τ_j, p_j) and (τ_{j+1}, p_{j+1}) , in intervals of 0.05 months. Thus \hat{P}_α becomes a vector $\hat{P}_\alpha \in [0, 1]^{\ell_\alpha}$ consisting of similarities for every 0.05 month, with length ℓ_α .

Data set	#students	#texts	#SIM
T_{train}	5418	70432	934720
T_{val}	989	12997	173536
$T_{analyze}$	3688	47666	N/A
Total	10095	131,095	1108256

Table 1: Data set overview.

These approximate profiles are then clustered. The clustering is complicated by profiles having variable length: \hat{P}_α has length ℓ_α depending on $\tau_{|T_\alpha|-m+1}$ (the time span between t_m and t_{T_α}), specific to α . Hence, distance computation used in the clustering algorithm is modified slightly; we compute the distance $dist(\hat{P}_\alpha, \hat{P}_\beta)$ between two profiles \hat{P}_α and \hat{P}_β by computing the Euclidean distance between the prefixes of length $\ell = \min\{\ell_\alpha, \ell_\beta\}$ of the two profiles:

$$dist(\hat{P}_\alpha, \hat{P}_\beta) = dist_E(\hat{P}_\alpha[1..\ell], \hat{P}_\beta[1..\ell]),$$

where $dist_E$ denotes the Euclidean distance, and $v[1..n]$ denotes the prefix of length n of vector v .

Similarly, when computing centroid C_r for cluster \mathcal{C}_r , profile \hat{P}_α contributes only to the ℓ_α first entries of C_r . Thus, with $\mathcal{C}_r^j = \{\hat{P}_\alpha | \hat{P}_\alpha \in \mathcal{C}_r, \ell_\alpha \leq j\}$, the j 'th entry of C_r is then computed as:

$$C_r[j] = \frac{1}{|\mathcal{C}_r^j|} \sum_{\hat{P}_\alpha \in \mathcal{C}_r^j} \hat{P}_\alpha[j]$$

where $v[j]$ denotes the j 'th entry of vector v .

The clustering is initiated by selecting k profiles at random as the initial clusters, and then continually reassigning profiles and recomputing centroids for clusters. Having reassigned the profiles, the cluster error E_C is computed as the average distance between any profile and the centroid of its cluster. The algorithm iterates until the change in E_C is sufficiently small ($E_C \leq 10^{-6}$), or until a set number of maximum iterations (100) is reached.

Selecting the number of clusters k is an inherent problem in all unsupervised learning tasks. We use the so called *elbow heuristic* which relies on looking at how the error decreases with the number of cluster and pick at the "elbow" in the resulting curve. For each of the resulting clusters, we compute a few statistics and writing quality indicators, such as *noun and verb phrases* (the ratio between nouns/main verbs and sentences respectively) [5], and the *simple measure of Gobbledygook* (SMOG) grade [4] (which estimates the grade level required for understanding the text).

3. EXPERIMENTS AND RESULTS

The data consists of around 130K essays by approximately 10K students, with an average length of about 6K characters. The data set was cleaned by removing very short (≤ 400) and very long ($\geq 30,000$) texts, in order to get rid of invalid essays (blank hand-ins, garbled texts, etc.). Proper pronouns were substituted with placeholder tokens and the first 200 characters of each text were removed, in an effort to remove any data identifying the real author of the text, that could be picked up by the neural network and lead to overfitting. Finally, authors with less than 5 texts were removed.

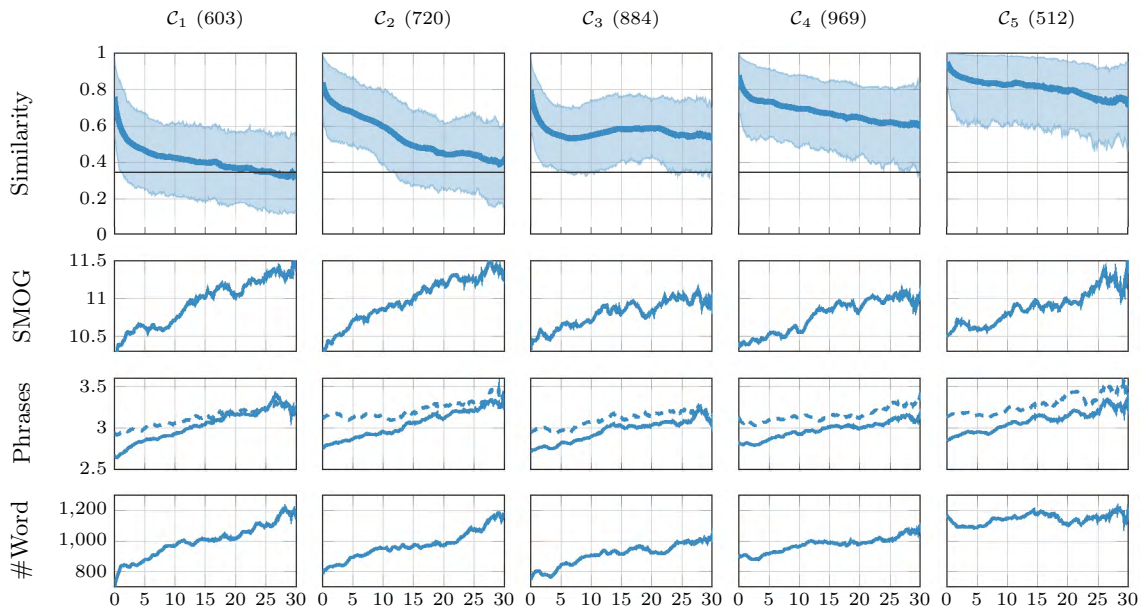

Figure 1: Plot of similarity curve, SMOG grade (incl. 90% intervals), noun/verb phrases (solid/dashed respectively) and average length (in words) for each cluster. The cluster size is given in parenthesis.

The resulting set is partitioned into two author disjoint sets: $T_{network}$ and $T_{analyze}$, used for training the network and performing the clustering respectively. $T_{network}$ is further split into author disjoint training and validation sets, T_{train} and T_{val} . The sizes of the sets are given in Table 1.

For training and evaluating the network, problem instances, consisting of pairs of texts, are constructed from T_{train} and T_{val} . A positive sample is created by selecting two texts from the same author, while a negative sample is created by sampling two texts from different authors. A 50:50 balanced data set is generated in this way². The number of instances (SIM) is shown in Table 1. The network is implemented using TensorFlow, and optimized for cross entropy using the Adam optimizer, using T_{val} for early stopping. For the clustering, each data point of $T_{analyze}$ simply consists of a single student and their texts, including meta data such as time of hand-in.

The profiles are constructed using $m = 2$. $k = 5$ is determined to be optimal using the elbow method and considering $k = 2, 3, \dots, 9$. Thus we obtain five clusters: C_1 , C_2 , C_3 , C_4 , and C_5 , with a cluster error of $E_C = 0.01407$. The curves representing the clusters (including cluster sizes and 90% distribution intervals) are shown in Figure 1³. The SMOG grade, the noun and verb phrases, and the average text length (in words) are also plotted. Furthermore, we sample two million random pairs of texts with random (different) authors, and compute the similarity for these samples, obtaining an average of 0.3470. This average is also plotted in Figure 1, while the similarity with respect to time is plotted as a heat map in Figure 2.

²We assume all claimed authors in the data to be the real authors; a few students may use ghostwriters or plagiarism, in which case some labels will be wrong.

³When visualizing and inspecting the clusters, we consider data until 30 months, as only few students are active longer.

4. ANALYSIS AND DISCUSSION

We start the analysis by considering the individual clusters found. When analyzing the clusters, three properties are important: the *initial value of the curve* describes the similarity between the second text of a student and their initial writing style, the *shape of the curve* describes the rate of change in writing style, and the *total change* describes how much the writing style has evolved. Furthermore, we will consider the mentioned indicators of writing style quality.

Across all clusters, the number of words written increases (with the exception of C_5), and the increase seems to be correlated with the corresponding decrease in similarity. Furthermore, students in all clusters appear to be improving with respect to the quality metrics on average. While positive, some clusters see a smaller increase than others, indicating that these clusters represents suboptimal development profiles.

C_1 and C_2 both represent students with a fairly large total change in writing style, and with a fairly high initial similarity. Both clusters also exhibit a large increase in the quality indicators (SMOG and phrases). The main difference is the rate of change of similarity; students in C_1 appear to change more rapidly in the first months before stagnation occurs, while students in C_2 appear to change more gradually. From a learning perspective, the development of students in C_2 seems superior. However, in terms of end result, it appears the writing quality of students in both clusters improves the same amount.

C_3 exhibits an interesting development pattern, in which the writing style appears to not only stagnate, but actually revert back, i.e. the similarity increases after the first year. This could be an indication of acquiring bad writing skills and 'unlearning' them again, or it could be an indication of learning new writing skills, but forgetting them again. In

Figure 2: Heat map showing the average similarity between different authors, depending on how long time the two authors have been in high school.

any case, it seems the development is suboptimal. This is further supported by the smaller increase in quality indicators compared to C_1 and C_2 .

Considering the total development of students in C_4 , the result appears similar to C_3 . Students only see a limited total change in both similarity and quality indicators. However, compared to C_3 , students do not appear to revert back, but rather exhibit a slow development. Compared to clusters C_1 and C_2 , the development still appears suboptimal.

Finally, C_5 appears to be quite distinct from the other clusters, with a higher-than-average initial similarity and SMOG grade, and the smallest total change in similarity among the clusters. The high initial SMOG grade indicates that C_5 contains initially strong students (wrt. writing), while the small change in similarity and SMOG grade (compared to C_1 and C_2) indicates stagnant development; this could be an indication, that schools do not manage to properly encourage/teach students, who are initially strong.

In summary, C_1 and C_2 appear optimal, while C_3 and C_4 appear suboptimal. While the development of C_5 seems suboptimal, the students are initially strong, and thus not as much a point of concern, as in C_3 and C_4 . Looking at the number of cluster members, we see that C_3 and C_4 are the largest individually, indicating that quite a few students are exhibiting suboptimal writing style development. However, the majority of students are located in C_1 , C_2 and C_5 , indicating optimal (or at least not at-risk) development through high school.

Figure 2 explores the similarity between different students across time spent in high school. As mentioned, the average similarity between random students is 0.3470.

The plot shows students starting out similar in writing style and then becoming less similar as time passes. Surprisingly, a first year student and a third year student are equally or more similar in writing style on average, compared to two different students in their third year. This might be explained by an initially small space of possible writing styles, which grows as students are educated. One might expect some writing styles would diminish or even disappear, but apparently, more new and diverse writing styles develop. While education is sometimes accused of destroying individuality and/or creativity, these findings indicate

the opposite, at least in regards to writing style.

5. CONCLUSIONS

We presented a method for analyzing writing style development, by training a Siamese neural network to compute a writing style similarity measure, and using this measure to construct and cluster writing style development profiles.

An analysis was performed on a data set consisting of Danish essays from Danish high school students. Five clusters were found. Using noun/verb phrases and SMOG grade, two were determined to exhibit suboptimal development, indicating students possibly at risk. Furthermore, we saw how students become less alike during high school, as their writing styles diverge and become more individual.

Learning Feature Analysis for Quality Improvement of Web-Based Teaching Materials Using Mouse Cursor Tracking

Mizuho Ikeda

ABSTRACT

In blended learning, it is meaningful to obtain data on and understand the nature of the usage of web-based teaching materials by individual students and by whole classes in progress. For this purpose, a system called MCTA1, which can detect the behavior of students' mouse cursors on web-based teaching materials in real time and visualize the analysis results, was developed. MCTA1 provides functions that collect specific granularity as subsections and visualize the result of analysis in real time. Through the application of this system in real classes, particularly in programming practice lessons, it became clear that the behavior of the mouse cursor was an effective source of information for determining how individual students and whole classes actually use the web-based teaching materials. This paper describes an outline of how the MCTA1 system works. The analysis of students' usage under the actual conditions of each subsection is shown using a Lorenz curve and Gini coefficient. Additionally, the result of the analysis of the web browsing order route of each subsection is shown using Ward's clustering method.

Keywords

Mouse Cursor Tracking, Learning Feature, Quality Improvement, Lorenz Curve

1. INTRODUCTION

With the spread of education via electronic mediums, under various specialized fields, studies on the learning style [1], the effects of the education method utilized [2], and the operability of these systems have been actively conducted.

In order to improve the quality of the content of the web-based teaching materials, it is important to analyze exactly how the students use these teaching materials in their classes. In blended-type education, it is necessary to grasp information on the usage of web-based teaching materials under real

conditions and determine the students' usage of these materials during actual classes in progress. In this situation, collecting the mouse cursor tracks is considered one of the effective means for determining their actual usage of the web-based teaching materials. Therefore, a system called MCTA1, which can detect the behavior of students' mouse cursors on web-based teaching materials in real time and visualize the analysis results, was developed. Since the system does not hang from the load that normally results from using special instruments on students, it can collect more precise data on the students' natural state. The quality of web-based teaching materials can be considered to consist of three components (curriculum composition, structure of web-based teaching materials, and lesson planning). The structured design of each quality component was drafted, and web-based teaching materials were constructed [3].

These materials have been used in blended learning sessions that use the e-learning system. The average number of members in a class is 25. Each session runs for 90 min, and each subject is performed over 14 sessions. The students who take the class belong to a department of liberal arts and are assumed not to have much knowledge of mathematical science and information science.

In this paper, a system that can detect the behavior of a student's mouse cursor is introduced. The action data from each subsection of the web-based teaching materials pages, which have been developed and implemented, were also discussed. Furthermore, the effect of analyzing the students' unique behavior via the segmentation granularity of the learning log is also described.

2. RELATED STUDIES

When LA research is roughly classified, it consists of the evaluation of the collection processes of (1) study data, (2) analysis, and (3) analysis result. From the point of view of detecting student behavior, learning the history data from the learning management system (LMS) as a collection of data in (1) above, the discovery of digital data, such as mouse cursor behavior [4], facial actions [5], eye tracking [6] has been studied using surveys of self-reported data. Moreover, in order to estimate it as an analysis (2) of the above, or the above-mentioned analysis result (3), various visualization techniques have been proposed. In a research on the learning style and actions of a student, most of the experiments applied limited experimentation and evaluation.

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 576 - 579

Figure 1: Web page composition and mouse cursor trackings.

These experiments were also performed in a restricted environment. There are few studies in real classes with conditions of continuous evaluation. Many analyses on the behavior of individual students have been conducted, but these studies often included only a few students and were limited by a lack of visualizations of group behavior.

When browsing a web page, the searcher tends to follow the mouse cursor with their eyes in order to easily click on the link of interest on the web page [7]. Based on this, the method of detecting the action of a mouse cursor is employed by this research. The system then detects whether the cursor would be in the position of a particular subsection based on the coordinate information built from the actions of many mouse cursors. The design and mounting were performed such that the automatic collection of continuous data could be realized, and a complete analysis of a student's features was conducted.

Section 3 describes the requirements for the functional enhancement of learning log collection, the system design of the action detection of a mouse cursor, and the mounting. Section 4 shows the system applied to a real classroom session and the effect of the feature analysis based on the learning log, subdivided according to the mouse cursor behavior data.

3. MECHANISM OF MCTA1

The web-based teaching materials used in real classes some pages consists of a menu, which contains the links to each section, and a section that is composed of several subsections.

At the top of each section, the subsection link is shown. Each indication range next to the subsection list is distinguished with a subsection number xy ($x = 0 \sim 9$, $y = 0 \sim 9$). Here, x shows the right and left domain, and y shows the top and bottom domain. Whenever the mouse cursor moves from one subsection to another, the numbers of the subsections that the cursor moves over in the process are sequentially collected automatically. The mechanism that collects both the subsection numbers and the time that a mouse cursor has been in existence has been developed.

Figure 1 is an example where the web-based teaching materials are comprised of five sections, and Subsection00 and a part of Subsection01 are displayed first. The shadowed area in the middle of Subsection01, Subsection02, Subsection12, and Subsection03 is shown. The arrow in Figure 1 is a trace of the mouse cursor tracks moved [Subsection00] → [Subsection01] → [Subsection02] → [Subsection03] → [Subsection12] → [Subsection01]. The y-axis direction is collected as the data "012321," and the x-axis direction is collected as "000010." At the same time, the time spent in each subsection is collected automatically.

The analysis and its visualization in real time are enabled by detecting the coordinate information, showing the action of a mouse cursor per subsection. The subsection of the middle position is only passed if the scroll bar is used and the trace data of the mouse can be collected sequentially. In addition, even if multiple windows such as when multiple tabs or separate windows are open are used alternately, the data can still be accurately collected.

4. VISUALIZING LEARNING FEATURE

By using mouse cursor tracking data, the distribution difference of the browsing subsections is validated. The data also allows checking of whether the browsing distribution of the web-based teaching materials does not result in a difference when the unique features of each student are analyzed. Here, a Lorenz curve and the Gini coefficient are used to evaluate the inequality of page browsing as a statistical value. In fact, these are commonly used statistics to express inequality, such as with income in economic science. As the Gini coefficient approaches 0, the Lorenz curve approaches the complete equality line, and the equability becomes high. As the Gini coefficient increases, the Lorenz curve keeps away from the complete equality line, income disparity decreases, and the equability decreases. The Lorenz curve, the complete equality line, and the Gini coefficient were used to analyze the reference time of each subsection of the web-based teaching materials.

The possibility of referring to each subsection equally becomes high, so that the Gini coefficient calculated from the accumulation reference time of web-based teaching materials approaches 0. In a blended-type educational setup, the students are expected to follow the footsteps to the subsection which the teacher is explaining and likely to refer to the said subsection. Therefore, the closer the Gini coefficient is to 0, the higher the possibility that the students are wandering around to another subsection. The higher the Gini coefficient, the lower the equability of the subsection reference. One subsection is more likely to be intensively referenced.

To determine the students' usage situation, clustering was then performed on the patterns of the browsing orders of the subsections. Ward's hierarchical agglomerative clustering method was adopted because it tended to be easy to clearly classify into a cluster.

4.1 Visualization using Lorenz curve

A Lorenz curve, represented by the values along the y-axis, is the cumulative relative frequency of the browsing time

(a) Level 2.

(b) Level 5.

Figure 2: Lorenz Curve (Level)

(a) Session 2.

(b) Session 13.

Figure 3: Lorenz Curve (Session)

of subsections, with its x-axis being the cumulative relative frequency of the browsing number of subsections used to visualize the inequality of the browsing time distribution. First, the browsing distribution according to each student's level, i.e., degree of subject achievement, was compared.

Based on achievement in the applied subject, the five steps for gauging the student's levels were evaluated, and a group division was carried out. The level is a five-step evaluation based on the number of tasks achieved for 38 subjects.

The Lorenz curve for level 2 is shown in Figure 2(a), and for level 5 is shown in Figure 2(b). Here, level 5 implies the level with the highest degree of subject achievement. The Gini coefficient was 0.45 at level 2 and 0.44 at level 5; therefore, the difference was not so apparent. Next the browsing distribution according to each lesson was compared. The browsing time distributions of the contents of the web-based teaching materials for all students of the 2nd session and the 13th session are indicated in Figure 3(a) and Figure 3(b), respectively. The Gini coefficient for the 2nd session was 0.41 and for the 13th session was 0.60. Compared with the first session time, the Gini coefficient tends to increase. This demonstrates that the inequality of the browsing distribution becomes high. Therefore, it is shown that the possibility of perusing one's subsection is high toward the second half of a lesson.

4.2 Time series display of Gini coefficient

The time series transition of the Gini coefficient in Figure 5 is a graph in which the session extends in the x-axis direction and Gini coefficient is set to the y-axis direction. The lower the Gini coefficient, the higher the browsing homogeneity. This shows that various subsections are browsed uniformly. The higher the Gini coefficient, the higher the uniformity. This shows that a few subsections are browsed intensively.

Figure 4: Patterns of browsing order.

The Gini coefficients of students from all levels except level 1 do not fluctuate very much. Particularly during the second half of the term (Sessions 8–14), the Gini coefficient of the levels 4 and 5 students maintain a relatively static state in a location for which it is high. In the first half of the term, the students browse not only the same subsections as the teacher, but other subsections as well. Therefore, the browsing distribution can encounter an inequality fluctuation for a short while. It later turns out that as the second half of the term progresses, the students become more concentrated in one subsection while browsing.

The level 2 students follow the teacher's browsing transition to the subsection, similar to what the level 5 students do in the first half of the term (Sessions 1–7). However, after Session 8, the homogeneity of the students' subsection browsing becomes much higher, and it seems to become clear that they browse various subsections, including past subsections, in addition to the subsections that the teacher browses.

In addition, the figure representing the time series of the Gini coefficient can be shown in real time. The teacher is able to confirm the non-homogeneity of the browsing distribution and adjust the speed of the teaching progress by returning to past subsections and lectures. Furthermore, it becomes useful in thinking about web-based material contents and the relocation of subsections.

4.3 Browsing order and route

Next, to clarify the students' features, representing their browsing behaviors, their browsing routes to each subsection were analyzed.

4.3.1 Patterns of browsing order

The students' mouse cursor tracks to each subsection are classified into the following four patterns. The pattern of where the mouse cursor came from and where it was moved to can be classified into the following four types (see Figure 4):

- (a) **IN before** : Move from one subsection to the target subsection in the same section
- (b) **IN over** : Move from one section to the target subsection
- (c) **OUT before** : Move from the target subsection to another subsection in the same section
- (d) **OUT over** : Move from the target subsection to another section

4.3.2 The graph of each cluster feature

According to these attributes, clustering is performed and a dendrogram is constructed by Ward's hierarchical agglom-

Figure 5: Transition of the Gini coefficient of each session (each student level).

Figure 6: Characteristic of the clustering result.

erative clustering method. In Figure 6, when height is set to 750, number of clusters is set to four. To confirm the four clusters' features, stacked graphs were created. According to the list of subsections of each cluster, the following features were clarified:

Cluster1 : Students browse repeatedly through various subsections without following the composition order of the subsection. It occurs in the subsection concerned with the beginners' tasks in the first half of the term.

Cluster2 : Like in "Cluster1," students browse repeatedly through various subsections without following the composition order for the subsection. However, the subsection is browsed more times than in "Cluster1." It is also occurring in the subsection concerned with basic tasks in the first half of the term.

Cluster3 : Students transferred from the subsection without following the order of subsection composition and transferred to the next subsection according to a composition order. It is occurring in the subsection concerned with the high difficulty level tasks in the second half of the term.

Cluster4 : Students transferred from the subsection according to a composition order and transferred to the other subsection without following the order of subsection composition. Like in "Cluster3," it is occurring in the subsection concerned with the high difficulty level tasks in the second half of the term.

Classifying subsections seems to help with the reconstruction of the web-based teaching materials so that students' understanding can be increased in stages.

5. DISCUSSION

Visualization using Lorenz curve, the time series transition of the Gini coefficient and the graphs of the clustering meth-

ods can be leveraged for information to support the class as the lessons progress. In addition, it was found that the results of the clustering of students' transition route is useful information for reviewing reconstruction, rearrangement, and speed adjustment of class progress, as the quality model of web-based teaching material.

6. CONCLUSION AND FUTURE WORK

A system to collect mouse cursor behavior automatically has been designed and developed. In addition, it has been applied to an actual class. Learning logs have also been collected. Furthermore, a system that can visualize in real time the progress of a lesson using the learning log has been developed. It was found that it is possible to clearly capture a student's learning activities. A learning log of the subsection units has been accumulated every semester since the 2015. A quality evaluation model of web-based teaching materials needs to be established by analyzing additional learner features (e.g., the students' learning style) and applying them to a mathematical model.

It's a Match! Reciprocal Recommender System for Graduating Students and Jobs

Anik Jacobsen and Gerasimos Spanakis

Maastricht University

Maastricht, 6200MD, Netherlands

anik.jacobsen@alumni.maastrichtuniversity.nl, jerry.spanakis@maastrichtuniversity.nl

ABSTRACT

Finding the perfect job that takes into account someone's skills and ambitions is an overwhelming challenge for many freshly graduated students. At the same time, companies struggle to hire employees fulfilling their requirements. Ideally, a successful match of students and jobs includes the preferences of both sides. This paper proposes a reciprocal recommender system matching graduating students and job offers. To construct a common representation space for the items of the recommendation, the course descriptions from the curriculum are used as a linking factor. Further, Latent Dirichlet Allocation (LDA) is used to extract topics from the course and job descriptions, forming the latent representation space. Next to providing job recommendations, curricula gaps can be discovered and thus the students can be better prepared for a future career. The algorithm is tested on data from a Data Science bachelor programme. Results show that a reciprocal matching of graduating students and jobs generates recommendations with precision and recall up to 0.7. The approach yields promising results for such system to be implemented as a job recommender system on university level or as a stand-alone system for graduating students.

Keywords

reciprocal recommender systems, job matching, Latent Dirichlet Allocation, discovering curricular gaps

1. INTRODUCTION

In recent years, most of the recruiting process has been shifted to online job portals and professional social networks, such as LinkedIn. Many graduating students feel overwhelmed by the available quantity and struggle to find a position that fits the curriculum of their degree, as well as the skills and interests developed during their studies. Moreover, employers are reluctant to employ freshly graduated students since they lack knowledge about the curriculum content and the skill sets of possible candidates. Many

degrees fail to address the requirements of job positions and often have gaps in the curricular, which make it difficult for students to start their career.

Job matching is a complex problem, as the employee candidate should fulfil the employer's requirements and the job should realise the candidate's ambitions. The situation is comparable to a dating scenario. The aim is to match students and jobs reciprocally, taking into account preferences from both sides. To do so, this paper proposes a reciprocal recommender system, matching graduating students and job offers based on the students' study curricula. To construct a common latent representation space, a probabilistic topics model is used, extracting topic distributions from the curriculum course and job descriptions.

The remainder of the paper is organised as follows: Section 2 presents related work in the domain of reciprocal recommenders and job recommender systems. In Section 3, the data and the proposed method used for generating recommendations are presented. After, in Section 4, the experiments are discussed and evaluated. Finally, Section 5 concludes the paper and presents future work.

2. RELATED WORK

Reciprocal recommenders are a class of recommender systems that consider the preferences of both items which are part of the recommendation, a match occurs when both sides benefit from a recommendation. The most significant research in the field has been done in social matching, especially online dating[1, 8] but also study buddy matching[9].

The process of recruitment has been shifted to an online environment. Thus, there is a high demand for sophisticated recommender systems. Yao et al. [7] propose a hybrid recommender system, taking into account user profiles and interactions. Their recommendations are based on a directed, multi-relational, weighted graph, whose structure is provided by the interactive features of a job seeking website. iHR+ is a mobile reciprocal job recommender system [10], which divides the information of job seekers into two categories: self-description and preference features. Recommendations are generated using the cross-similarity among these features. Similar to the approach presented in this paper, Ding et al. [5] focus their reciprocal job recommender system on current graduating students. Their system takes historical student information, as well as the preference of employers and students into account. Using the grading in-

Anik Jacobsen and Gerasimos Spanakis "It's a Match! Reciprocal Recommender System for Graduating Students and Jobs" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 580 - 583

formation of former and current graduates, they determine candidates (in terms of employers and students) similar to comparable students.

In the domain of generating recommendations using probabilistic topic models, Apaza et al. [2] propose a content-based recommender system for online courses. They use LDA to derive topic distributions as descriptive feature vectors for the courses. Combining this with the students' historic grading information, they are recommending courses to students with weaknesses.

This paper focuses on matching graduating students with jobs. The common latent representation space is formed by the course and job descriptions. The students' grading information is used as a preference and strength indicator. Thus, there is no intermediate step explicitly stating the preferences for both sides of the recommendation. Developing a job recommender system based on topics derived from course and job descriptions is new in the domain of reciprocal recommenders.

3. PROPOSED METHOD

3.1 Data

The data used for the recommendation has to describe three items: the jobs, the courses, and the students.

The job offers were scraped from indeed.com, to obtain realistic data. indeed.com is a job search engine. It obtains its entries from multiple sources, such as company websites, postings created on indeed.com itself or job boards. The target positions were derived from alumni data. The keywords "junior" or "entry-level" made it possible to identify job offers suitable for freshly graduated bachelor students. Further, the scraping was limited to job offers in the English language, to ensure comparability with the course descriptions. Eventually, 103 job offers were collected, suitable for someone with a Bachelor degree in Data Science.

The programme's student guide provides a course description for each course in the curriculum. They are phrased according to the Dublin Descriptors, which provide information about the content and structure of a course, as well as the competences acquired in a course.

Overall 72 student grading data points were used. It was obtained from two sources: anonymised student information from 2011 to 2015 (44 students) and grading information from 28 current students in their final year. All the grades are in the range from 1 to 10.

3.2 Recommendation Algorithm Description

An overview of the recommendation algorithm is displayed in Figure 1. In summary, first, the student grades are normalised. Then, a Latent Dirichlet Allocation (LDA) model is trained and applied on a corpus consisting of the job postings and course descriptions. The resulting topic distribution matrices are used to compute a similarity matrix of the jobs and courses. Combining the similarity matrix and the normalised student grades, a score is computed, allowing to generate ranked recommendation lists for students (recommending jobs) and jobs (recommending students).

Figure 1: Pipeline of the recommendation algorithm

3.2.1 Normalising Student Data

To obtain successful matches for all students, the grading information needs to be normalised. Examiners grade in different ways. This grading bias is removed, by subtracting the mean in the course dimension from each datapoint. The aim of using the grades is identifying strengths and interests of the students. To obtain a "strength profile" per student, the mean in the student dimension is subtracted from each datapoint. Lastly, the grades which have a missing value are replaced with zeros. Students did not attend the course and thus they should have a zero weight for the final score.

3.2.2 Applying LDA and Constructing Similarity Matrix between Courses and Jobs

Topic models are statistical models for discovering abstract topics that appear in a corpus of documents. In the application, Latent Dirichlet Allocation (LDA) is used. It was introduced by Blei et al. in 2003 [4]. The model is based on the assumption that each document is a combination of topics and each topic is a probability distribution over words [3]. From a set of documents and a fixed number of topics, LDA returns a set of words associated with each topic with a probability. Applying the trained model to a document gives a probability distribution for the topics.

To compare the course descriptions and job postings, feature descriptors for the text documents need to be constructed. Assuming that each course description and job offer includes a certain set of topics and there is a set of relevant words describing the topics, a probabilistic topic model (LDA in this case) can be used to describe the topics of the documents. The model is first trained on the corpus consisting of the course and job descriptions. 12 is chosen as the number of topics for the algorithm because content analysis of the topics showed this was the optimal number.

The result of applying the trained LDA model to the corpus is a feature vector per document, expressing the probability of each topic. The vectors are combined in two matrices, one describing the courses and one describing the jobs. The cosine similarity is used as similarity measure. The resulting similarity matrix gives the similarity for each course and job respectively.

3.2.3 Calculating Score and Ranking Recommendations

The final score for each student and job combination is a matrix multiplication. The courses are the linking factor between the students and jobs. Thus, the score is calculated by multiplying the normalised grades per course of each student with the similarity matrix of courses and jobs. This is formalised by Equation 1.

$$score_{s,j} = \sum_{c=1}^M grade_{s,c} * sim_{j,c} \quad (1)$$

where s is the student, j is the job and c is the course. M is the number of courses. As the final recommendations, the jobs with the top k scores for each student (ranked), and the students with the top k scores for each job (ranked) are recommended.

4. EXPERIMENTS AND RESULTS

An appropriate evaluation of the recommender system requires the deployment of the system and feedback from students and recruiters. In this case, it is only possible for a part of the students. Prabhakar et al. [9] propose measures to evaluate a reciprocal recommender system using the available data. Next to evaluating the experiments using the proposed measures, recommendations generated by deploying the algorithm were sent to the 28 current final year students to obtain qualitative feedback.

4.1 Evaluation Metrics

A successful reciprocal recommendation includes the preferences of both sides. Thus, it can be said that “Student y is a successful (reciprocal) recommendation for job x (out of the k -total), if and only if, job x is also in the recommendation list of student y .”. The same holds for the job recommendations to students. Based on this logic and the precision and recall measure modified by [9] we can formalise precision and recall as follows:

$$P_x = \frac{N_x}{k}, R_x = \frac{N_x}{N_{*x}} \quad (2)$$

where P_x is the precision for student/job x , R_x is the recall for student/job x , N_x is the number of successful recommendations for student/job x (as defined before), k is the total number of recommendations generated and N_{*x} is the number of jobs/students that have x in their recommendation list. The total precision and recall of all recommendations can be computed using the following formulae:

$$P = \frac{1}{M} \sum_{i=1}^M P_i, R = \frac{1}{M} \sum_{i=1}^M R_i \quad (3)$$

where P_i and R_i are the precision and recall respectively for student/job i (as defined previously) and M is the total number of students/jobs.

The results of the recommendation system are two recommendation lists, one recommending jobs to students and one recommending students to jobs. Precision and recall are first calculated separately for the students (P_S, R_S) and the jobs (P_J, R_J), thus per recommendation list. For the final measure, the mean is computed.

Another measure proposed by Prabhakar et al. [9] is the Discounted Cumulative Gain (DCG). Originally, it has been developed for the field of information retrieval to measure the quality of rankings [6]. It was adapted by Prabhakar et al. to measure rank alignment or reciprocity [9]. A perfect rank alignment and thus an indicator for a good reciprocal system is described by: “For all students/jobs i , present at position j in the recommendation list of job/student u , if u is also present at the same position j in the recommendation list of i ”. Dividing it by the number of successful recommendations ensures that all values are in the range $[0, 1]$. If there are no successful recommendation for student/job u , the gain is 0. The formula is defined as:

Figure 2: Precision graph, including the standard deviation.

Figure 3: Recall graph, including the standard deviation.

$$DCG = \frac{1}{M} \sum_{u=1}^M \frac{\sum_{j=1}^k g_{uij}}{S} \quad (4)$$

where M is the number of students/jobs, S is the number of successful recommendations, j is the rank and g_{uij} is the gain of job/student i (at position j) for student/job u . The gain is given by:

$$g_{ui} = \frac{1}{1 + |diff_{ui}|} \quad (5)$$

where $diff_{ui}$ is the difference in ranks of student i in the recommendation list of job u and job u in the recommendation list of student i . The same holds for job i and student u . Thus, the gain is 1 when the rankings between a student and a job are the same; otherwise, the gain is discounted. As before, the DCG is calculated separately for students (DCG_S) and jobs (DCG_J). Then, the mean is computed.

4.2 Quantitative Results

The recommender system is evaluated on the data described in section 3.1. The recommendations are ranked according to their score and the top-k [5,10,15,20,25,30] jobs/students are recommended. Because of the LDA topic model, there is some randomness involved in the process. 50 runs of the experiments are conducted and precision, recall and DCG scores are recorded. The results are averaged across the runs, for each top-k recommendations. The precision, recall and DCG graphs are shown in Figures 2, 3 and 4. The standard deviation is displayed as a stability indicator.

Precision and recall increase with the number of recommendations given. Giving more recommendations increases the probability of successful recommendations. The low variance shows that the results are reliable. Reaching a precision score of 0.657 and a recall score of 0.705 with $k=30$ recommendations indicates that most matches generated by the system are successful.

Figure 4: DCG graph, including the standard deviation.

The decreasing value of the DCG with recommendations given can be explained by the increasing difference in ranks in the recommendation list. The peak at $k=10$ (DCG score 0.221) indicates that a number of 10 recommendation is optimal to provide students and jobs with the most rank aligned recommendations. In the case of a job recommender system, a successful recommendation is more important than rank alignment. Thus, precision and recall scores provide a better insight into the quality of the recommender system. Overall, the precision and recall measures show that the reciprocal approach generates successful recommendations, matching students and jobs effectively.

4.3 Qualitative Results

The 28 last year students who gave access to their data were provided with their top 10 recommendations and were asked to re-rank them. To analyse the results, the DCG was used, as a measure of rank alignment between the original and re-ranked rankings. The DCG score for comparing the original and re-ranked entries with each other is 0.472. Since all items are represented in both lists, the DCG score is an average of the gain of all recommendations for all participants. Thus, a DCG score of 0.472 indicates that on average, each posting was re-ranked 1 or 2 rankings below or above its original ranking (since $\frac{1}{2} > 0.472 > \frac{1}{3}$). Some change in the ranking was to be expected because some of the job offers were similar to each other. The result supports that the order of the recommendations was appropriate.

The students were also asked to give qualitative feedback on their recommendations. The overall feedback received from the students was positive. Most reported that they received interesting input for future career perspectives. However, one drawback revealed by the feedback is the limited possibility of expressing interests and ambitions. Incorporating this information in the recommendation algorithm is a future direction.

5. CONCLUSION AND FUTURE WORK

This paper proposes an algorithm that matches graduating students and jobs reciprocally, simplifying the overwhelming job search for graduating students and allowing employers to recruit graduated students more effectively. It was shown that the system can be deployed to generate successful employment couples. The items of the recommendation are solely represented by the academic information from the students and the descriptions of the jobs. Courses are used as a linking factor, a common representation space for academic courses and jobs was established using LDA. Finally, quan-

titative results, based on measures introduced by Prabhakar et al. [9], show that the reciprocal approach is an appropriate way to generate successful matches. The feedback from students in their final year showed that the results could be used for career inspiration, however, a way to express preferences is desired.

The work presented in this paper provides many opportunities for further experimentation and improvement. Course preferences from the student side could be included to recommend jobs that better fit the ambitions and interests of the students. Moreover, feedback from the employer perspective could lead to new insights on how to enhance the algorithm to better match the recruiters' needs. The results could be used to discover curricular gaps in the study programmes. Some job descriptions might include topics which are not addressed by the courses. Tackling these issues would lead to students better prepared for the business world and its requirements. The implementation of the algorithm was limited to one programme. More (real-life) experiments would be useful to evaluate further and improve the system. Long term deployment of the algorithm within a suitable platform would lead to advanced conclusions.

ABSTRACT

Student retention is a major challenge at American universities with the average six year graduation rate hovering around 59%. Among minority students the graduation rate drops to 46% for Blacks and 55% for Hispanics. Low graduation rates not only impact the financial well-being of individuals but the economy as a whole. Thus, improving student retention, in particular, minority student retention, is of paramount importance at institutions of higher education. This paper describes a machine learning approach to predicting minority native and transfer student dropout using a dataset from a four year Hispanic serving institution in the north eastern region of the United States with a large percentage of minority students. The results of the study show that standard machine learning models can predict minority transfer student dropout with a high degree of accuracy of 97% and minority native student dropout with an accuracy of 81%. The features that were most important in predicting minority transfer student dropout were SAT scores, and college cumulative GPA, while high school GPA and college cumulative GPA were the top predictors for minority native student dropout. This study demonstrates that educational institutions can use cost effective off-the-shelf standard machine learning models to achieve a high degree of accuracy in predicting minority student dropout. The high prediction accuracy achieved helps in reliably identifying at-risk minority students and providing them with necessary interventions to support their academic success.

Dropout prediction, Minority student retention, Machine learning models, At-risk students

1. INTRODUCTION

Student retention is a major challenge at American universities with the average 6 year graduation rate hovering around 59% [14]. Graduation rates vary with institutional selectivity [18]; the situation being particularly grave at institutions with open admission policies where the 6 year average graduation rate is at a meager 32% [14]. There is substantial variation in the graduation rates by race and ethnicity. African American students had the lowest six year graduation rate at 46% while Hispanic students'

graduation rate is at 55% [14]. Transfer student graduation rates are also low at 42% [14]. Thus, improving student retention, particularly for minorities, is of paramount importance at institutions of higher education.

A critical factor in increasing student retention is the ability to accurately identify at-risk students, so that relevant interventions can be provided. But, there is a paucity of literature focused on predicting minority student dropout and even less literature that considers native and transfer students separately, taking into account their individual characteristics. Minority students' graduation rates are among the lowest and they have different characteristics, needs and face different challenges in college. Hence analyzing and modeling their dropout rate separately is warranted. It would also be informative to model the transfer and native students separately as these students have different characteristics and different graduation rates. Such an analysis could be used to identify, target and customize interventions differently to minority transfer and native students and hence lend better support for their success in college.

This paper describes a machine learning approach to predicting minority college student dropout, treating native and transfer students separately. The objective of this paper is not to build an esoteric novel machine learning model hitherto not seen in the literature, instead, we aim to show the effectiveness of standard off-the-shelf machine learning models in predicting minority student dropout. To the best of the authors' knowledge this study is one of the first to employ machine learning techniques to build separate models to predict minority transfer student and native student dropout taking into account the unique characteristics of each. Thus, this study contributes to the literature by demonstrating that standard machine learning models can achieve a high degree of accuracy in predicting minority student dropout by taking into account the different characteristics of native and transfer students. This high prediction accuracy can then be used to reliably identify at-risk students and provide them with the necessary intervention to support their success. This study also contributes by giving readers an idea of which machine learning models work well in this domain, what data preprocessing is needed and what features have good predictive power. Further, this study contributes to student retention practice as it demonstrates that easy to implement and cost effective off-the-shelf machine learning models can achieve a high degree of accuracy in identifying minority students at risk of dropping out.

2. LITERATURE REVIEW

Research on student attrition has traditionally been based on surveying student cohorts and following them to assess drop out. These surveys contributed to the building of theoretical models of student retention, the most famous of them being the Tinto model

J.D Jayaraman, Sue Gerber and Julian Garcia "Supporting Minority Student Success by using Machine Learning to Identify At-Risk Students" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 584 - 587

[17]. These survey based research have been criticized for being too specific to an institution and hence not generalizable [6]. An alternative to survey based research is to use the data that most higher education institutions routinely collect about their students. This type of research based on institutional databases has been shown to be comparable to survey based research [4].

There are numerous factors that affect student retention. Tinto [17] highlights academic difficulty, adjustment problems, lack of clear academic goals, lack of commitment, inability to integrate with the college community, uncertainty, incongruence and isolation as factors involved in student dropout. Tinto's theory of student integration posits that past and current academic success are crucial factors in determining student attrition and many studies have found high school GPA and SAT scores to have a strong effect on student retention [18]. Declaration of major and number of credit hours taken during the first semester have been used as proxies for institutional and goal commitment.

Transferring from one educational institution to another also has an impact on retention rates. Factors affecting transfer student academic success and persistence include issues regarding institution support [9, 23], financial factors [7], student goals [11] and familial support [1, 10].

When it comes to minority students Moffat [13] found that SAT scores were not a strong predictor of student success for Black students. A key challenge to success minority students face in predominantly white institutions is a sense of alienation due to underrepresentation [15]. Hoffman [10] found that student satisfaction and success can be strongly linked to cocurricular involvement for minority students.

Research on using machine learning techniques to predict student attrition is still in its infancy. Delen [8] and Thammasiri [16] used several machine learning methods such as support vector machines and neural networks to model freshmen student attrition and found that support vector machines performed best, reaching a prediction accuracy close to 80%. Lauria, Baron, Devireddy, Sundararaju, and Jayaprakash [12] used demographic and course related data to show that support vector machines performed better than decision trees at predicting at-risk students.

This study uses many of the factors impacting student retention identified in the literature to build machine learning models to predict student attrition. Factors unique to transfer students, as identified in the literature, are used to build specific models to predict transfer student dropouts.

3. CONCEPTUAL FRAMEWORK

The study is broadly based on the models of student retention developed by several researchers, one of the earliest and popular being that of Tinto [41]. Tinto's model suggested that student success is determined by the degree of academic and social integration. Other popular models of student retention include Bean's student attrition model [2, 3] which takes the employee turnover approach suggesting that students dropout for similar reasons as employees leave an organization and the Cabrera, Nora & Castenada [6] model which integrates the Tinto and Bean models. Based on these models several studies have identified factors that impact student dropout. High school GPA, SAT scores, number of credit hours taken during the first semester, declaration of major, aid based on academic achievement and student loans are among the factors that are predictive of student dropout.

Our study attempted to collect data on various factors based on the

theoretical models and the predictive factors that have been identified based on them and use them as features in our machine learning models.

4. METHODOLOGY

4.1 Data

This study used five years (2011 – 2015) of minority student data from a regional Hispanic serving four year college in the north eastern region of the United States. The university is an urban university catering to a largely minority population (80% minorities). The university accepts a large number of transfer students from the local community colleges and other institutions. The overall four year graduation rate at the university was around 55%, with the graduation rate among transfer students at 61% and native students at 45%. Table 1 presents some descriptive statistics of the dataset.

Table 1: Descriptive Statistics

Native Students		Transfer Students	
Number of students	3897	Number of students	4703
Female	58%	Female	65%
Male	42%	Male	35%
Hispanic	55%	Hispanic	48%
African American	30%	African American	34%
Asian	11%	Asian	15%
Other race	4%	Other race	2%
Mean age	19	Mean age	28
Mean GPA	2.50	Mean GPA	2.99
Mean SAT Math	450	Mean SAT Math	413
Mean SAT English	430	Mean SAT English	390

We define a student to have dropped out if he/she does not enroll in the year following the last semester of enrollment. Based on this definition we constructed a binary indicator variable to indicate whether a student has dropped out or not. Both the transfer student and native student dataset had about 35% dropouts.

4.2 Features

Table 2 shows the features that were used in the machine learning models.

Table 2: Features

Features used for both native and transfer students
Age
Gender
Race
High School GPA
Gateway Math Status (gateway math course is required or not)
Gateway English Status (gateway English course is required or not)
Math placement (Has student completed the developmental math requirement)
English placement (Has student completed the developmental English requirement)
Cumulative GPA
Trend in the GPA over the semesters enrolled (Increasing, Decreasing, Stable)
SAT Math
SAT English
Difference between credits taken and credits earned
Community involvement (Student belongs to clubs and other student organizations or not)

Has student declared major (yes or no)
Additional features used only for transfer students
Difference between number of college credits applied for transfer and accepted for transfer.
Marital status
Highest degree earned prior to transfer

The features we used broadly fell into the following categories: student achievement, performance and progress, community engagement and demographics. We engineered several of the features from the raw data. From the raw data on GPA we extracted a feature indicating the trend in the GPA. From the credits taken and credits passed data by semester, we computed the difference of total credits taken and passed. The raw data also had information on clubs and other community activities that the student participated in. From this we created a binary variable indicating whether the student participated in community activities or not. For the transfer students we used additional features more relevant to them. Since the mean age of the transfer students (28 years) was much larger we used marital status and highest degree earned as features in the transfer student models.

4.3 Analysis

Student retention data sets are typically imbalanced as the number of dropouts is usually much less than the number that don't. Our dataset was imbalanced with around 35% of dropouts. If the data is imbalanced the standard classifiers have a bias towards the larger majority class. One approach to correcting this imbalance is to preprocess the data in order to balance it out and then build the model. This approach uses various techniques to either oversample the minority class or undersample the majority class or a combination of both. Synthetic Minority Oversampling Technique (SMOTE) is a popular and robust technique that uses a combination of oversampling the minority class and undersampling the majority class which results in better classifier performance [6]. We tried various techniques to correct the imbalance and found the SMOTE technique to yield the best results. Hence our study used SMOTE to correct the imbalance.

We used the features described above and imbalance corrected data to build the following machine learning models: Naïve Bayes, Logistic Regression, Decision Tree, Support Vector Machine, Random Forest, Extreme Gradient Boosting (XGBoost), and a Voting Ensemble model. We chose these models as they are popular classification models some of which have been used in the extant literature. The ensemble model XGBoost has been shown to have high performance in numerous datasets in different domains. The Voting Ensemble is a stacked ensemble model consisting of all of the other models mentioned above. All of the above models were built using 75% of the data for training and 25% for testing and using a 10 fold cross validation to avoid overfitting.

5. RESULTS

The prediction results of the models we trained above are shown in Table 3. Accuracy is a good and intuitive performance measure for balanced datasets. Since we have corrected the imbalance in our dataset prior to building our models, we have reported Accuracy as our measure of performance for the models. The AUC measure and the F1 score were very close to the accuracy measure, so, we have not reported them here, but the information is available on request.

Table 3: Dropout Prediction Results

Model	Accuracy	
	Native Student	Transfer Student
Naïve Bayes	71.3%	40.2%

Support Vector Machine	79.9%	81.2%
Logistic Regression	78.8%	81.4%
Random Forest	79.0%	97.0%
Extreme Gradient Boosting	81.3%	97.1%
Voting Ensemble	80.9%	97.4%

Table 4 shows the features ranked by importance. We have only reported the features that had a score of greater than 1% as the rest have negligible predictive power.

Table 4: Features Ordered by Importance

Native Students		Transfer Students	
Feature	Score	Feature	Score
Cumulative GPA	0.135	SAT English	0.261
High School GPA	0.103	SAT Math	0.191
SAT English	0.100	Cumulative GPA	0.149
SAT Math	0.097	Age	0.093
Difference credits taken and earned	0.095	Difference credits taken and earned	0.063
Age	0.074	Difference credits accepted and applied for transfer	0.047
Gateway English Status	0.051	GPA trend	0.043
English placement	0.046	Community involvement	0.031
Community involvement	0.046	Declared major	0.025
GPA trend	0.046	Developmental Math	0.021
Developmental Math	0.031	GPA trend	0.021
Gender	0.021	Gender	0.013
Race	0.013	Highest degree	0.010

6. DISCUSSION

This study demonstrates how standard machine learning models can be used to predict, with a high degree of accuracy, students at-risk of dropping out. To the best of our knowledge this is one of the first studies to focus on predicting minority student dropout and in particular minority transfer and native student dropout using standard machine learning techniques. The high prediction accuracies achieved in this study demonstrates the effectiveness of standard machine learning models for predicting undergraduate minority student dropout. Reliable identification of at-risk students can help in providing timely interventions to support the student's success and thus increase student retention. Any educational institution can adopt the approach demonstrated in this study with relative ease. A discussion of the various classifiers and the feature importance follows.

The Naïve Bayes classifier, as expected, performed the worst on both the native student and transfer student dataset. In the native student dataset the Extreme Gradient Boosting (XGBoost) model performed the best reaching an 81% accuracy. In the case of transfer students again the XGBoost, Random Forest and the Stacked Voting Ensemble all reached a very high 97% accuracy rate. This very high accuracy rate was indeed surprising as we did not expect to be able to achieve such high performance. All of these models performed much worse without imbalance correction, thus, pointing to the importance of correcting for imbalance in this domain. The results also show that different models perform better between native and transfer students with different features being

important, stressing the importance of modeling these student bodies separately.

For native students their college GPA and high school GPA seemed to be the strongest predictors of dropout. This is consistent with prior literature and the conceptual framework we based the study on. The other factors that had reasonably good predictive power were SAT scores and the difference between credits taken and earned. For transfer students the SAT scores were the strongest predictors with college GPA being the next strongest. Surprisingly High school GPA did not seem to have any impact on transfer student dropout prediction, unlike in the case of native students. This is inconsistent with the literature that has found high school grades to be good predictors of college success [5,15]. One potential explanation could be that the transfer students in our sample are older and thus far removed from high school and hence the high school GPA does not have much predictive power.

Another surprising result was that race did not have much predictive power for both the native students and transfer students. Given the racial gap in graduation rates, even among Black, Hispanic and Asian students, we expected to find some relationship between race and dropout, but found none. Similarly gender did not have much predictive power either. Community involvement was a fairly strong predictor of dropout for both the native and transfer students. This is consistent with the theoretical models of student retention used in our conceptual framework that highlight student engagement as a key factor in college success.

There are several limitations to our current study. The performance results that we have obtained are specific to our sample and caution should be exercised in generalizing them. However, our results do give readers and researchers an idea of the possible accuracy that can be achieved by using standard machine learning models to predict minority student dropout and what features are important. Also, our results can be very informative for institutions with a similar minority student profile as ours. Another limitation is that we have not considered any financial aid data, and other factors not related to academic achievement such as personality traits etc. These are all avenues for further research that we are currently pursuing.

7. CONCLUSION

The results of our study demonstrate that standard machine learning techniques can be effective in predicting minority student dropout with a high degree of accuracy. We also show that different models perform better between transfer students and native students thus reinforcing the importance of modeling these two student bodies separately.

The practical implication of this study is that it demonstrates that educational institutions can use their existing databases that contain routine student data and standard off-the-shelf machine learning models to accurately predict at-risk minority students. This is a cost effective way for institutions to identify at-risk students so that they can devote their resources to offering interventions aimed at retaining them.

ABSTRACT

dAFM introduced a neural network implementation of the Additive Factors Model, allowing backpropagation to be used to learn or improve an expert Knowledge Component model. This neural approach learned continuous weights corresponding to item to KC associations. In this work, we extend dAFM to support learning of binary item to KC associations by employing a modification of backpropagation from the literature, called BinaryConnect.

1. INTRODUCTION

An association of items to knowledge components (KC), known as a Q-matrix, is a necessary prerequisite for many models of cognitive estimation used in the educational data mining community and in practice in intelligent tutoring systems [3]. Additive Factors Models (AFM) have been used to refine a Q-matrix by searching through the space of operations (e.g., merge and split) using an expert KC model and other factors of items [4]. Recently, a neural networks approach to modeling and fitting the Q-matrix was introduced which uses backpropagation and stochastic gradient descent to refine the Q-matrix as represented by as a weight coefficient matrix between the item input layer and a hidden layer in the network. This approach, called dAFM [5], results in continuous valued associations between items and KCs. While continuous values in a Q-matrix may open up interesting new interpretations of partial associations, this fuzzy association is not standard. To produce standard binary associations, the weights could be rounded to 1 or 0. This was done in the original dAFM paper but always resulted in accuracy worse than the continuous valued Q-matrix, and often times performed worse than using the original expert Q-matrix. In this paper, we implement a binary weight learning procedure into the fitting process and demonstrate that this approach achieves accuracy better than the original Q-matrix and rivaling that of the continuous valued Q-matrix.

2. RELATED WORK

Several variants on binary weight learning in neural networks have been introduced in the machine learning literature. The primary motivation of these approaches has been to reduce memory size and speed up neural network training, with embedded systems applications in mind. BinaryConnect [1] is one approach that stochastically samples binary weights based on real-values in the forward and back propagation and then updates the weights. Binarized Neural Networks [2] constrain not only weights but also activations to between 1 and -1, which reduces the model size and replaces multiplication with a logical operation. The XNOR-Net [6] approach introduced an extra scaling layer to approximate the parameter and activation by a binary tensor and a scaling factor. Shayer et al.[7] introduced a probabilistic training method, the LR-nets (Local reparameterization networks), which trains the binary weights by introducing a good smoothing approximation and then using its derivative.

As BinaryConnect is an established method and our objective was to get binarized weights in a single specific layer instead of binarizing all weights and activations, we choose BinaryConnect for its simplicity, abundance of public code, and good fit to our task of binarizing Q-matrix learning within dAFM.

3. BINARY CONNECT

BinaryConnect proposes two ways to binarize weights. One is a deterministic sign function, which assigns 1 if the weight is bigger than 0 otherwise assigns -1.

$$w_b = \begin{cases} +1 & \text{if } w > 0, \\ -1 & \text{if otherwise.} \end{cases} \quad (1)$$

The other one is to stochastically assign +1 with probability p and -1 with probability $1-p$ with a 'hard sigmoid' function.

$$w_b = \begin{cases} +1 & \text{with probability } p = \sigma(w), \\ -1 & \text{with probability } 1 - p. \end{cases} \quad (2)$$

$$\sigma(x) = \text{clip}\left(\frac{x+1}{2}, 0, 1\right) = \max\left(0, \min\left(1, \frac{x+1}{2}\right)\right) \quad (3)$$

During the SGD training of binary connect, weights are only binarized in the forward pass and gradient computation, and the float versions of the weights are updated. This is because the real-valued weights are needed in the updating process

Nan Jiang and Zachary Pardos "Binary Q-matrix Learning with dAFM" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 588 - 590

in SGD.

4. BINARY dAFM

Our goal is for the associations between questions and knowledge components (KC) to be represented by the more interpretable binary instead of continuous weights; accordingly, we implement BinaryConnect into dAFM and describe the technical implementation in this section. Considering the real meaning of the associations, we constrain the weights to 1 and 0 instead of 1 and -1. The binary weight learning adapted to dAFM is as follows:

Algorithm SGD training with BinaryConnect in dAFM. C is the cost function and `binarize()` and `clip()` are the functions that binarize and clip weights.

Require: previous weights in the QK layer WB_{qk} , Qk layer, the layer before the QK layer—the step_input layer, b_{t-1} : bias and learning rate η .

Ensure: updated parameter w_t and b_t

1. Forward propagation:

$WB_{qk} \leftarrow \text{binarize}(Wqk_{t-1})$
compute QK knowing step_input, WB_{qk} , b

2. Backward propagation:

get the Qjk layer's activations gradient $\frac{\partial C}{\partial(qk)}$
compute $\frac{\partial C}{\partial(\text{step_input})}$ knowing $\frac{\partial C}{\partial(qk)}$ and WB_{qk}

3. Parameter update:

compute $\frac{\partial C}{\partial(WB_{qk})}$ and $\frac{\partial C}{\partial(Qk)}$ and step_input
 $Wqk_t \leftarrow \text{clip}(Wqk_{t-1} - \eta \frac{\partial C}{\partial(WB_{qk_{t-1}})})$
 $b_t \leftarrow b_{t-1} - \eta \frac{\partial C}{\partial(b_{t-1})}$

Programatically, this translated to the following modifications to the dAFM code, including definition of a BinaryDense neural network layer and Binarization function:

```
if binary=="False":
    Q_jk = TimeDistributed(Dense(skills,
        activation="linear",
        kernel_initializer=self.f(Q_jk_initialize),
        use_bias=False, trainable=qtrainable),
        trainable=qtrainable, name="Q_jk")(step_input)
else:
    Q_jk = TimeDistributed(BinaryDense(skills,
        activation="linear",
        kernel_initializer=self.f(Q_jk_initialize),
        use_bias=False, trainable=qtrainable),
        trainable=qtrainable, name="Q_jk")(step_input)
```

BinaryDense layer

```
self.w = self.add_weight(shape=(input_dim, self.units),
    initializer=self.w_initializer,
    name="w",
    regularizer=self.w_regularizer,
    constraint=self.w_constraint)
self.binary=binarize(self.w, H=self.H)
output = K.dot(inputs, self.binary)
```

Binarize function

```
def binarize(W, H=1):
    Wb = H * binary_tanh(W / H)
    return Wb
def round_through(x):
    rounded = K.round(x)
    return x + K.stop_gradient(rounded - x)
def _hard_sigmoid(x):
```

```
x = (0.5 * x) + 0.5
return K.clip(x, 0, 1)
def binary_tanh(x):
    return round_through(_hard_sigmoid(x))
```

In our binary dAFM Model implementation, we integrate a Keras implementation¹ of a BinaryDense layer. Specifically, we manage the backpropagation of the binarized weights and update the real-valued weights using the `tf.stop_gradient()` function.

5. RESULTS

Results of dAFM models' predictions using a 30% test set hold-out on our four primary datasets are shown in Table 1. The AFM model represents the baseline standard model with its expert Q-matrix. The Binary dAFM model (hard sigmoid) represents the model that uses the hard sigmoid function and Binary dAFM (sign function) represents the model that use the sign function to binarize. The RMSE is reported on the model's prediction of the correctness of student first attempt responses to items in datasets from the Cognitive Tutor and ASSISTments.

We can observe that the original dAFM model with continuous valued Q-matrix associations beats the original expert KC model (AFM) in all datasets, a result observed in the original paper. We can also observe that the hard sigmoid variants of Binary dAFM performed better than the sign function variant in three of the four datasets. Additionally, the hard sigmoid Binary dAFM performed better than the original AFM model in all datasets, a departure from the rounded approach which performed worse than AFM on the majority of datasets. In one case, with ASSISTments 2012-2013, the Binary approach even beats continuous valued dAFM, scoring a substantially lower RMSE of 0.4339 compared to 0.4443. We conclude from these observations that the BinaryConnect approach to binarized weight learning is an effective alternative approach to continuous Q-matrix association representation with neural networks.

5.1 Replication

1. Clone the github repository.

```
1 git clone https://github.com/CAHLR/dAFM.git
```

2. Enter into dAFM directory using following command.

```
1 cd dAFM
```

3. Execute the `src/main.py` script using python after specifying the input values. It will train on a specified portion of the dataset serving as the training set and evaluate the average root mean square error on a specified validation set portion. By Passing different values as arguments, different datasets and models can be trained and evaluated.

```
1 python3 src/main.py --dataset G0 --dataset_path
2 G0/Geometry96-97 --user_id 'Anon Student Id' --
3 problem_id 'question' --correctness 'test' --sk
4 ill_name 'KC (Original)' --dAFM fine-tuned No --
5 save_model False --binary True
```

See the github README for additional options

ABSTRACT

To overcome space and time limits in education environment, online education is becoming increasingly crucial. Most online education is based on video lectures. Video-based lectures are delivered to the learner through the language of the instructor. Hence, the language (word) of the instructor affects learners during the video discourse. In this study, we examined the effectiveness between emotional (positive and negative) and non-emotional (neutral) words for learning effectiveness on online education based on video lectures. The results indicated that learners remember emotional words better than non-emotional ones. If educational content based on video lectures is implemented using emotional words, then it will improve the learning effectiveness in online education through video lectures.

1. INTRODUCTION

The scale of online education service market is gradually expanding at present because of the development of technology and interest in education. The demand for online education is also increasing as education transcends regional and temporal boundaries. An example of these phenomena is massive open online course (MOOC). MOOC refers to online learning that

allows anyone to enroll in free courses on a large scale without a restriction in the number of students. In 2008, MOOC offered educational opportunities to learners and allowed them to take lectures from prestigious universities online [1].

Online education services, such as MOOC, facilitate learning through video lectures; thus, learners acquire knowledge by watching the video lectures [2,3]. In such an environment, determining whether the learner has actually watched the video lecture or not is important. This problem is a considerably challenging task because we can monitor the learner based only on a limited range of data, that is, the interaction between the learner and computer.

The common technique in addressing this issue is to assess whether the learner is watching the video lecture by solving the relevant quizzes or simply checking the playing time of the video. The method of judging whether a learner watches a video lecture through quizzes can evaluate the learner's understanding level. However, constructing relevant quizzes and completing these quizzes are time consuming for both the instructor and learners, respectively [4]. Moreover, the sharing of quizzes among learners may lose its original purpose. Hence, the method of checking the playing time of the video is not an accurate evaluation technique because it recognizes that the learner has watched the video even when the learner is performing other tasks or is absent. Through the short-term memory, we can assess whether learners watch the video lecture or not. Therefore, in this study, we developed a short-term memory judge system.

This short-term memory judge system determines whether or not a learner has watched the video lecture through cognitive processing based on the frequency effect of the word used in the video lecture. In this work, we consider that emotional words can improve a learner's memory better than non-emotional ones; hence, we analyzed the effectiveness of emotional words. The

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 591 - 594

results indicated that even in the short-term memory judge system, learners remember emotional words better than neutral ones.

The paper is organized as follows: Section 2 presents research related to this study; Section 3 describes the short-term memory judge system; Section 4 discusses experimental evaluation; and, finally, Section 5 provides a conclusion as well as notes on future research.

2. RELATED WORK

2.1 Learning Judge System

Online education services are based on video lectures, and various studies have been conducted to enhance learning experience in self-directed learning environments. Jang (2011) analyzed the learning attitudes of e-learning students through electroencephalogram (EEG) and provided feedbacks according to the learner's learning attitude. He also examined the correlation between the learning attitude and EEG to improve the learning efficiency of students. Consequently, distinguishing when to concentrate on learning and when not is possible. Another limitation is that actual EEG equipment is necessary and is influenced by the surrounding environment [5]. Lee (2009) developed a platform to gauge the response speed to voice and visual stimuli, assessed the language performance effectively, and applied it to improve learning. The platform concurrently measured the speed and accuracy for language processing. Hence, speed and accuracy were observed to enhance language learning [6]. Kim (2014) analyzed the patterns of thousands of learners watching online video lectures and determined the dropout and interaction peak. Accordingly, the high dropout rate was noticed in videos with long playback time. Hence, video playback time can be an important factor affecting the learning outcome [7]. Mills (2011) analyzed how mind-wandering occurs during learning using an intelligent tutoring system. The result of the experiment indicated that an average of 11.5 mind-wandering occurred with an interval of 2 min [8]. Given that mind-wandering frequently occurs in an online education environment, automatically detecting the occurrence of this event is also crucial. Various studies and methods have been conducted and proposed to enhance learning effectiveness in an online education environment. However, they remain remarkably challenging because the learning effectiveness can be assessed based only on very limited data, that is, the interaction data between the learners and computers only.

2.2 Emotional Words

Research on the memory between emotional and neutral words has been conducted in the field of cognitive psychology. Kensinger & Corkin (2003) and Ochsner (2000) reported that emotional words are easier to be recalled than neutral words [9,10]. Another research was conducted in the field of natural language processing to classify whether sentences have a positive or negative meaning through emotional words [11]. Esuli and Andrea et al. (2007) proposed *SentiwordNet* to efficiently categorize the positive and negative meaning of words [12]. In this work, we evaluated the difference of memory retention between emotional and neutral words using the short-term memory judge system. We also utilized the existing *Korean Emotional Word Dictionary* to distinguish the difference among positive, negative, and neutral words [13].

3. SHORT-TERM MEMORY JUDGE SYSTEM

The short-term memory judge system can automatically detect whether mind-wandering occurs in video lecture-based online education. To detect the short-term memory, the system determines whether mind-wandering occurs while the learner is watching the video lecture. To assess whether mind-wandering occurs, we applied the word frequency effect theory of cognitive psychology. The word frequency effect indicates the difference in cognitive responses between high- and low-frequency words. The theory is that a difference in cognitive responses exists between the words that people actually know and the words they do not recognize. The system judges the short-term memory by calculating the learner's word recognition response through a word game. The word game spontaneously generates high-frequency words of the video lecture viewed by the learner and words not set in the video lecture. Moreover, the learner can actually see a randomly displayed word from the automatically generated word set in the word game and selects the correct answer. Figure 1 shows developed word game UI.

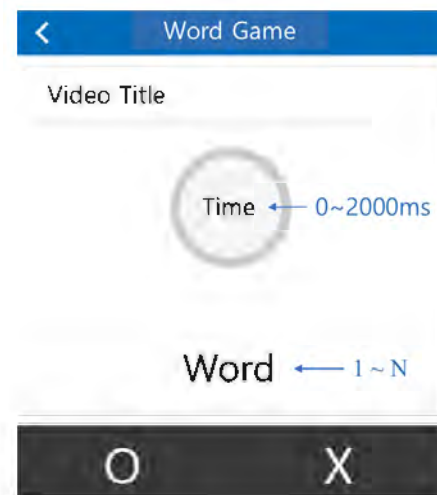

Figure 1. Word Game UI

The short-term memory judge system is automatically determined as Pass or Fail based on the correct word rate and response rate in the word game. According to cognitive psychology, the speed of recognizing words that people know is between 0.7 and 1.2 s. Therefore, the existing cognitive response rate theory was applied as a criterion for the detection. Considering that the word game is implemented in web environment, 0.3–1.7 s is set as the word recognition response criterion, which was added with 0.4–0.5 s [14].

4. EXPERIMENTAL EVALUATION

4.1 Dataset

To verify the idea of this study, data were collected using short-term memory judge system from 576 students who take the university major courses in Korea. The data contain user information, video lecture information, frequent words, response time, and correctness information. By using the response time and correctness rate, we determined whether or not the learner has actually watched the video lecture. The number of video lectures

used in the system is 77, and the number of words used is 17,592 (Table 1). We classified the emotional words into positive and negative and classified non-emotional words into neutral. These data have a total of 3,158 positive, 3,283 negative, and 11,151 neutral words [13]. Generally, considering that neutral words are more common than emotional ones, the sum of the neutral words is much higher than the emotional words in this data set. The list of positive, negative, and neutral words is presented in Table 2. The total number of the gathered data is 47,517.

Table 1. Data sets of the positive, negative, and neutral words

# of data sets	# of users	# of contents	# of words
47,517	576	77	17,592

Table 2. Example of positive, negative, and neutral words

Positive	Negative	Neutral
Happy	Destroy	Office
Thanks	Fight	Research
True	Difficult	Drama
Joy	Lie	Bank
Positive	Unhappy	Apartment

4.2 Analysis & Results

We have calculated the average response time and correctness of each emotional word to analyze the effectiveness of emotional words using the short-term memory judge system. High correctness value indicates that the learner memorizes the word well from the lecture, whereas the low response time denotes that the learner rapidly responded to the word. The calculated results are presented in Table 3.

Table 3. Average of correctness and response time per emotional word

	Correctness (%)	Response Time (ms)
Positive	0.811	919.7
Negative	0.688	924.2
Neutral	0.519	898.3

The interpretation of the calculated results should consider both the correctness and time. Correctness is the highest with a positive word of 0.811. The negative word has lower correctness than the positive word but is better than the neutral word. Meanwhile, the neutral word has the lowest score of 0.519. Response time is the fastest with the neutral word at 898.3ms and slowest with the negative word at 924.2ms. However, it can be interpreted that around 900ms are word recognition time according to cognitive psychology.

The analyzed result indicates that emotional words are better remembered by learners than non-emotional words. Alternatively, constructing video-based education content with emotional words can enhance learning effectiveness because it reflects the learner's memory better than that with non-emotional words.

5. CONCLUSION

To examine the effectiveness of emotional information of words by using the short-term memory judge system, we have analyzed the data based on emotional information of words applying the data gathered from the system. Finally, we can confirm that emotional (positive and negative) words have more influence on learners than non-emotional (neutral) words. When we construct an educational content based on video lecture through emotional words, we conclude that this method can promote considerably effective learning.

Our future work includes constructing a system that introduces word emotional information to the short-term memory judge system and analyzes the effectiveness of word emotional information profoundly through experimentation.

ABSTRACT

For many forms of e-learning environments, the system's behaviors can be viewed as a sequential decision process wherein, at each discrete step, the system is responsible for deciding the next system action when there are multiple ones available. Each of these system decisions affects the user's successive actions and performance and some of them are more important than others. Thus, this raises an open question: how can we identify the critical system interactive decisions that are linked to student learning from a long trajectory of decisions? In this work, we proposed and evaluated Critical-Reinforcement Learning (Critical-RL), an adversarial deep reinforcement learning (ADRL) based framework to identify critical decisions and induce compact yet effective policies. Specifically, it induces a pair of adversarial policies based upon Deep Q-Network (DQN) with opposite goals: one is to improve student learning while the other is to hinder; critical decisions are identified by comparing the two adversarial policies and using their corresponding Q-value differences; finally, a Critical policy is induced by giving optimal action on critical decisions but random yet reasonable decisions on others. We evaluated the effectiveness of Critical policy against a random yet reasonable (Random) policy. While no significant difference was found between the two condition, it is probably because of small sample sizes. Much to our surprise, we found that students often experience so-called *Critical phase*: a consecutive sequence of critical decisions with the same action. Students were further divided into High vs. Low based on the number of Critical phases they experienced and our results showed that while no significant was found between the two Low groups, the High Critical group learned significantly more than the High Random group.

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 595 - 598

1. INTRODUCTION

Intelligent Tutor Systems (ITSs) are a type of highly interactive e-learning environment which facilitates learning by providing contextualized feedback and step-by-step support to individual students [4, 14]. These step-by-step behaviors can be viewed as a sequential decision process where at each step the system chooses an action (e.g. give a hint, show an example) from a set of options. During tutoring, the system makes a series of decisions to provide adaptive instructions. Some of the decisions might be *more important and impactful than others*. This raises a major open question: ***How can we identify the critical system interactive decisions that are linked to student learning especially in a long trajectory of decisions?*** For example, in our ITS, the tutor makes more than 400 sequential decisions during training.

Reinforcement Learning (RL) offers one of the most promising approaches to data-driven decision-making applications and RL algorithms are designed to induce effective policies that determine the best action for an agent to take in any given situation so as to maximize some predefined cumulative reward. A number of researchers have studied the application of existing RL algorithms to improve the effectiveness of ITSs [2, 13, 12, 3]. However, relatively little work has been done to analyze, interpret, and explain RL-induced policies. While traditional hypothesis-driven, cause-and-effect approaches offer clear conceptual and causal insights that can be evaluated and interpreted, RL-induced policies are often large, cumbersome, and difficult to understand. In this work we propose to induce compact RL policies that highlight key or critical decisions by taking advantage of the structure of the domain and the structure of our induced policies by leveraging the conditional independence relationships among the state features.

We propose Critical-RL, an adversarial deep reinforcement learning (ADRL) based framework to induce compact policies that make critical decisions. By inferring critical decisions we can identify which tutor actions are minimally necessary for the tutoring process to be effective, which holds great implications for systems research. Additionally, inference of critical relationships is one of the central tasks of science and it is one of the most challenging topics in many disciplines, particularly in the areas where controlled experiments are comparatively expensive or even impossible. In this work, we propose a general framework that fully integrates automatic critical inference and standard

reinforcement learning in an ITS setting. We expect that our framework can be spread to other similar domains for related critical tasks.

2. RELATED WORK

2.1 Applying RL to ITSs

Prior work has applied a variety of RL approaches to induce pedagogical policies to improve the effectiveness ITS [1, 6, 15, 10]. For example, Beck et al. [1] applied temporal difference learning on simulated students to induce a policy that would minimize student time on task. Results showed that the policy group indeed spent significantly less time than the non-policy group. Shen et al. [13] applied MDP to induce a pedagogical policy aimed at improving students' learning performance. Results showed that the induced policy was significantly more effective than a random baseline policy for certain learners. Mandel et al. [6] applied a POMDP based approach to induce a pedagogical policy targeted at improving students' learning gain. The RL-induced policy was then compared with an expert policy and a random baseline policy. Results revealed that the RL-induced policy significantly outperformed the other two. Wang et al. [15] applied a variety of deep RL approaches on simulated students to induce pedagogical policies that would improve students' normalized learning gain in an educational game. Simulation results suggested that deep RL policies were more effective than linear model based RL policies.

To summarize, prior work has shown that RL induced policies can lead to improved student learning/behavior as compared to baseline policies. However, prior work has mainly focused on inducing effective policies from pre-collected data or simulated student, but put relatively less effort to identify the exact part that makes them effective.

2.2 Deep Reinforcement Learning (DRL)

Recent advance in deep learning has allowed RL to work in complex interactive environments which was often impractical in before. Recent work showed that RL can induce effective policies for a variety of tasks, such as game playing [8, 9], robotic control [5, 19], recommendation generation [17, 16] and also ITS control [15, 10]. However, all of the state-of-art RL algorithms focused on inducing effective policies. None of them considered interpreting, explaining and identifying critical decisions from RL induced policies.

2.3 Exploiting Q-value Difference

Some prior work has exploited the Q-value difference between actions to simplify the decision-making process/problem. For example, Mitchell et al. [7] relied on the Q-value difference to select features for RL. They proposed a Q-value difference based policy evaluation metric, which was then used to guide feature selection for RL. Zhou et al. [18] relied on Q-value difference to reduce the policy space. More specifically, they applied weighted decision tree with post-pruning to extract a compact set of 529 rules from a full set of 3706 rules. During the extraction, each rule was weighted by the Q-value difference between two alternative actions and thus increased the carry-out likelihood of more important decisions. Results showed that the full RL policy and the compact DT policy together were significantly more effective than a random policy and there is no significantly

difference between the full RL policy and the compact DT policy.

In sum, prior studies have used Q-value difference to measure action importance and results suggest that it is an effective measure. However, prior work used Q-value difference to reduce the feature space or the policy space, but we used it to reduce the decision space.

3. METHOD

3.1 Adversarial Reinforcement Learning

Adversarial Reinforcement Learning (ARL) is a category of RL which can induce a pair of policies for opposite goals. In our application, an *Original Policy* was induced using the original rewards and an *Inversed Policy* was induced using the inversed rewards, which is the negative value of the original rewards. We expect these two policies to have opposite goals, one to help student learn while the other to hinder them learn.

3.2 Deep Q-Network (DQN)

Deep Q-Network (DQN) is a RL algorithm that uses a deep neural network to approximate the Q-value function. The neural network takes a state as input, which is represented as a numerical vector, and outputs its estimation of the Q values for all possible actions. During training, the neural network is updated recursively following the Bellman equation shown below until converge.

$$Q_{i+1}(s, a) = \mathbb{E}_{s' \sim \epsilon} [r + \gamma \max_{a'} Q_i(s', a') | s, a] \quad (1)$$

where γ is a discount factor, ϵ is the environment and Q_i is the action-value function at the i th iteration. DQN is a *model free* approach that it is focused on estimating the action value functions from the interactions with the environment without constructing a model of the environment. Also, it is an off-policy approach that the new policy is induced based upon the historical data generated by an alternative behavior policy.

3.3 Identifying Critical Decision

Once the adversarial policies are induced, critical decisions are identified following two rules: 1) given the state, the two policies make opposite decisions and 2) the decision is important for both policies.

For a given state, rule one is tested first. If the two policies make the same decisions, it is not critical. Otherwise, rule two is tested. In order to measure the importance of the decision for each policy, we calculate the absolute Q-value difference between the two alternative actions: $\Delta Q^*(s) = |Q^*(s, a_1) - Q^*(s, a_2)|$. If this difference is greater than a threshold, the decision is considered important for the corresponding policy. In this paper, we set the threshold to be the median Q-value difference for all decisions in our training data set.

3.4 Critical Policy Induction

In tutoring, our ITS provides students with the same 12 problems in the same order. Among them, the first and the

eight problems are fixed to be problem solving where the students is required to solve all the steps. For the rest 10 problems, the policies decide whether to elicit the next step from the student or to directly show the student how to solve the next step.

Thus, we induced 10 pairs of adversarial policies, one for each problem. Each pair of the adversarial policies consist of two policies: an original policy and an inversed policy. The original policy was induced using the original rewards while the inversed policy was induced using inversed rewards. Other than the rewards, all other parts of the data were identical, such as state representation and transition samples.

In order to find the best policy, for each problem, we implemented two different types of neural network: Recurrent Neural Network (RNN) and Long Short Term Memory (LSTM) to induce the adversarial policies. The policies were then evaluated using Per decision importance sampling (PDIS)[11] and the better one was selected. Once the adversarial policies were induced, whether a decision was critical or not during tutoring was determined following the two rules mentioned in section 3.3.

Finally, the Critical policy is carried out partially in that if a decision is critical, it will be carried out; otherwise, the decision will be made randomly. More specifically, for a given state, the adversarial policies are queried to determine whether the decision is critical. If it is, the decision made by the original policy will be taken; otherwise, a random decision will be taken.

4. EXPERIMENT SETUP

In order to evaluate the critical-RL induced policy, we conducted a classroom study comparing the Critical policy with the Random policy. The participants of this study were undergraduate students enrolled in the Discrete Mathematics class at the Department of Computer Science at NC State University in 2018 Fall. In this study, all students were required to complete 4 phases: 1) pre-training, 2) pre-test, 3) training on Pyrenees tutor, and 4) post-test. Pyrenees tutor is a web-based ITS for probability, which covers 10 major principles of probability such as the Complement Theorem and Bayes' Rule. During the experiment, all students in both two conditions studied the same materials, received the same questions in pre-test, trained on the same tutor, examined the same questions in post-test. The only difference was the policies used in the tutor.

In this study, 120 students were randomly assigned to the Critical condition and the Random condition. Due to preparation for final exams and the length of the study, 96 student completed the study. 3 students performed perfectly in the pre-test were excluded from our subsequent statistical analysis. The final group sizes were: $N = 50$ (Critical) and $N = 43$ (Random). We performed a Chi-square test of the relationship between students' condition and their completion rate and found no significant difference between the conditions: $\chi^2(1) = 2.55, p = 0.11$.

5. RESULTS

Table 1 shows the mean and standard deviation (SD) of the post-test score, learning gain (LG) and total training time for the Crucial and Random condition. Contrast comparison analysis showed no significant difference between the two conditions on all three measures. Please note that although the Critical condition appeared to outperform the Random condition on learning gain (0.05 vs. 0.03), such difference was not significant ($p = 0.50$). One of the possible reasons is that the group size was not large enough to demonstrate significance. A post hoc power analysis revealed that a total sample of 1544 students was required to detect significance at .05 on small effects ($d=.14$), with 80% power using a contrast.

Table 1: Critical vs. Random

Measure	Critical	Random	P value
Post	0.71 (0.19)	0.71 (0.20)	0.91
LG	0.05 (0.18)	0.03 (0.14)	0.50
Time	121.6 (37.7)	116.3 (30.47)	0.46

Since the Critical policy was partially carry-out where only critical decisions were made following the optimal policy, we conducted an inspection into the relation between the number of critical decisions made and student learning. Through analyzing the student-system interactive logs, we found that critical decisions were always appeared in groups and each group of consecutive critical decisions had the same action. This is aligned with existing learning theory that the learning process is a continuous process. Student can stay in the same learning state during several steps but this continuous learning state is hard to be represented by current features. In other words, in the same learning state, the agent will continuous giving same actions to the student until he moves to next learning state. So, we defined *Critical Phase* as a period of consecutive critical decisions executions with the same action according to the Critical policy.

In order to analyze the impact of critical phase, we divided students into High vs. Low groups by a median split on the number of critical phases they experienced. For the Random condition, as the execution of decisions were partially agreed with the Critical policy, we ignored the actual decision and only focused on the Critical policy's decision. Thus, we had four groups based upon their critical phase number and policies: High-Random ($n=20$), Low-Random ($n=23$), High-Critical ($n=27$), Low-Critical ($n=23$). A two-way ANOVA analysis using policies {Critical, Random} and critical phase {High, Low} as two factors and the student's learning gain as the dependent measure showed a significant interaction effect $F(1, 89) = 7.163, p = 0.009$. Subsequent contrast analysis revealed that the High-Crucial group ($M = 0.098, SD = 0.2$) significantly outperformed High-Random group ($M = -0.011, SD = 0.16$): $t(89) = 2.360, p = 0.02$. However, such difference was not significant between the Low-Crucial group ($M = 0.001, SD = 0.13$) and Low-Random group ($M = 0.067, SD = 0.12$): $t(89) = 1.42, p = 0.16$.

In terms of time on task, a two-way ANOVA analysis on condition and critical phase number showed a main effect on critical phase number: $F(1, 89) = 5.579, p = 0.020$ in

Figure 1: Comparison of Learning Performance

that the High group ($M = 127.51, SD = 36.34$) spent significantly more time on task than the Low group ($M = 110.56, SD = 30.51$). The results suggest that students experienced more critical phases are more likely to spend more time on task.

6. CONCLUSION

In this study, we proposed Critical-RL to identify critical pedagogical decisions in an ITS. Based on the ADRL framework, we induced a Critical policy which gives optimal action on critical decision points but randomly select actions on others. We empirically compared the Critical policy with a baseline Random policy in a classroom study for real students. Although there's no significant difference between the two conditions, we found the existence of Critical phase, a consecutive sequence of critical decisions with the same action. We then divided students into High vs. Low groups based on the number of Critical phases they experienced. Results showed that while the two Low groups were not sensitive to pedagogical policies, the High-Critical group significantly outperformed the High-Random group. This suggested that for certain students, the Critical policy is significantly more effective than the Random policy.

In the future, we plan to analyze the difference between states in critical and non-critical phase. Through analyzing the critical state, we hope to align critical decision with existing learning theory and further generalize our method to other domain.

ABSTRACT

This paper deals with adaptive learning technologies that fit the individual learner's needs. Thereby, recommender systems play a key role in supporting the user's decision process for an efficient and effective item selection. Activity data have been collected from students using course materials available online. The courses provided access to the course materials via a novel web application. This app also presented learning recommendations to make the content selection more efficient and effective. The paper focuses on the Smart Learning Recommender System which utilizes a novel knowledge-based filtering approach. The algorithm transfers multi-contextual activity data into time-dependent user models. The resulting relevance scores represent the individual user's need to learn specific learning objects at a particular point in time of the course. In comparison to the evaluation results of other educational recommender systems on the same datasets, the introduced approach produces the most precise time-sensitive recommendations.

Keywords

Educational Recommender Systems, User Modeling, Knowledge-based Filtering, Time-Dependent Recommendations

1. INTRODUCTION & RELATED WORK

Recommender Systems are designed for users who lose track of the vast quantity of items available and thus need assistance with their item selection [14]. This paper presents a recommender systems (RSs) for educational closed-corpus settings, which means that the learning environment adapts to the learners' needs within a self-contained course [13]. The user interface offers content recommendations at particular points in time that fit with the current needs and the contextual situation of individual course participants. The most important task of the recommender system is to support learners in achieving their personal learning goals. An

"appropriate" recommendation in this context aims at making learning more efficient and effective by supporting the content selection process [15].

Most researchers borrow traditional Content-based Filtering and Collaborative Filtering algorithms and, at least partially, adapt them to the domain of Technology Enhanced Learning instead of directly applying the same approaches [3]. Bauman and Tuzhilin [1] categorized educational recommender systems either as "knowledge enhancing" which aims at broadening the knowledge to new topics or as "remedial" which aims at filling identified knowledge gaps of previously studied items. Closed-course RSs, such as the one introduced in this work, aim at solving both issues. They assist the learners in reaching their personal or course-specific goals which require new topics to be learned and the consolidation of already acquired knowledge. An exhaustive literature review on recommender approaches for curriculum planning and the prediction of appropriate item sequences in courses is presented in [7].

The remainder of the paper is structured as follows: Section two introduces the overall Smart Learning Recommender with the time-dependent learning need and the Top-N scoring, followed by the determination procedure for optimal factor weights. Section four presents the results of different evaluations. Finally, this paper ends with a description of its limitations and a conclusion.

2. SMART LEARNING RECOMMENDER

The Smart Learning Recommender (SLR) presented in this paper is utilized by the Smart Learning Companion App [8] – a mobile web application¹ that was used by about 600 learners from different institutions so far (until February 2019). Thereby, the web app is the only entry point for students to access courses, learning objects, and lecture dates as well as to get recommendations for the next best contents to be learned and triggers the tracking of all relevant user interactions. A course is usually structured in learning units which themselves contain low-level learning objects (LO) that can be texts, exercises, videos and so on. The hierarchy however can have more levels. The content creators and teachers provide a lot of metadata on each low-level LO based on the Learning Resource Meta-data Specification (LOM), the

Question and Test Interoperability Specification (QTI) and the Common Cartridge Specification (CC). Among others, the metadata include attributes on prerequisite LOs, information on the exam relevance of an item, on the typical learning time and on the learning objectives. Interactions with all items are stored as Experience API (xAPI) statements.

The educational recommender system aims at identifying the learning need of a user u for an item i . The learning need is a score that takes the currently approximated knowledge and other related properties (time of the lecture, prerequisites, etc.) as well as the required amount of knowledge into account. The user-item-pair is presented by a relevance score $rscore_{u,i}$ having the value from 0 to 1, where 0 indicates the lowest relevance and 1 indicates the highest possible relevance. The relevance score defines a time and context dependent value and is expressed as a time dependent function: The relevance function $rf_{u,i}(t)$ of user u for item i is derived from several sub-functions $rf_{u,i,x}(t)$ of individual factors x_1, \dots, x_n , as a function of time t , each representing another context (cf. [6]). A detailed description of the factors, including the mathematics, can be found in [7]. All factors are in the range of [0,1] and represent the learning need. The considered factors per user, item and time are:

1. **Self-assessments:** A student can explicitly define his / her knowledge level at particular points in time on a 1 to 5 stars scale
2. **Interaction with items:** This factor indicates how much of the available material for a learning object was accessed by a student
3. **Processing time of an item:** This factor indicates how long the student learned a learning object. It is 0 when the student needed exactly the intended time and between 0 and 1 if he /she needs more or less time as defined in the metadata
4. **Performance in exercises:** The percentage of wrong answered questions represents the relevance of the exercise factor
5. **Fulfilled prerequisites:** The more a student learned the underlying learning objects, the higher the relevance score of the subsequent items
6. **Lecture times:** The lecture times factor indicates the timely relevance of a learning object for face-to-face lectures
7. **Item relevance for the course goal:** learning objects that are more relevant for exams show a higher relevance score than optional contents – in terms of a constant value defined in the Learning Resource Metadata Specification.
8. **Collaborative learning need:** The relevance functions of similar users on this learning object are taken into account in order to offset underestimations and bad learning plannings for the current user.
9. **Human memory and forgetting effect:** After learning an object, the gained knowledge will slowly decrease over time. After each learning iteration, the forgetting factor is set to 0 and then slowly increases again.

For the calculation of recommendations, all single-factor functions are weighted. The weighted average of all factors describes the total learning need of item i for that user u and is calculated as

$$rf_{u,i}(t) = \frac{\sum_{x=1}^n (w_x * rf_{u,i,x}(t))}{\sum_{x=1}^n w_x} \quad (1)$$

Here w_x is the weight of a single factor x in $\{x_1, \dots, x_n\}$ and n is the number of factors (cf. [6]). The overall recommendation engine analyses the current learning need values of the requesting student for all items in the course. Thereby, the model of the SLR can be created offline: The relevance functions are computed at regular intervals by processing all existing user-item-time-triplets. When a user requests recommendations, the relevance scores for all items are calculated on demand by considering the current time value for t . Afterward, the items are sorted by their learning need value. The result is a Top-N list of items beginning with the highest relevance scores that represent the most important learning units or learning objects for the student that needs to be learned at that time.

3. TIME-DEPENDENT WEIGHTS

In order to evaluate the ideal weights for different factors at various points in time that will lead to the most appropriate recommendations, different methods have been analyzed – from equal weights, over manual adjustments, up to linear models that calculate appropriate weights per course week. At the beginning of the development of the Smart Learning Recommender, the weights were set to a value of 1 in order to have a starting point from which to present recommendations to learners. The method that generates the weights which leads to the highest precision values is realized with the help of an Artificial Neural Network (ANN). RapidMiner² is used with a neural network for regression problems that contains just one hidden layer. One input vector represents a user-item-time triplet. The input vector comprises $n + 1$ input features which are the n factor relevance values of the SLR (per user, item and time). Additionally, the first input value per node is set to a value of one, which makes it a node-specific bias. The node's output o_k is the predicted value (e.g., the overall learning need) for the user-item-time triplet. The training values for the output are 1 if this item i has been accessed by the user u in the last week before the split t and 0 if not. The node's output is calculated as:

$$o_k = \varphi\left(\left(\sum_{x=1}^n rscore_{u,i,t,x} * nw_{x,k}\right) + b_k\right). \quad (2)$$

In contrast to the actual intention of an Artificial Neural Network, where the predicted output values o_k are of interest, the approach in this work targets the determined weights of the trained nodes. Thereby, each of the nodes contains a weight vector \overrightarrow{NW}_k . This weight vector has the same number $n + 1$ of dimensions as the ANN has as input features (where the first weight represents the bias b_k). The activation function φ is a sigmoid function which is common for ANNs that aim at solving linear problems. The resulting weights fit the requirements of the SLR weighting formula presented in Formula 1. If the hidden layer contains more than one node, the weights per factor x are averaged according to the node's bias b_k which results in a final weight w_x

²RapidMiner. See: <https://rapidminer.com/>

Figure 1: Comparison of the evaluated approaches including the Smart Learning Recommender (each given in the best setting); left: Average precision per course week; right: Timeliness values given in minutes per course week.

of factor x :

$$w_x = \frac{\sum_{k=1}^K n w_{x,k} * b_k}{\sum_{k=1}^K b_k}. \quad (3)$$

K is the number of all nodes in the hidden layer. The determined weight w_x for each factor is subsequently applied to the factor weight algorithm of the Smart Learning Recommender given in Formula 1. An exhaustive description of the approach is presented in [7]. With a sample of 50 nodes, the ANN reaches the highest average precision that is 0.4% better than the precision of other linear models and even 10.9% more precise than the utilization of equal weights.

4. EVALUATION

We compared the Smart Learning Recommender approach to four other approaches. The first recommender system is the basic Slope One algorithm as Collaborative Filtering (CF)-baseline as introduced by Lemire et al. [12]. Lemire et al. considered this approach only theoretically for Technology Enhanced Learning (TEL) [11] and it has only been rarely applied in education contexts as mentioned by Verbert et al. [16]. The second algorithm extends the Slope One approach with time-weights [5]. This time-based algorithm is applied in the context of Technology Enhanced Learning for the first time. Another Item-based Collaborative Filtering approach, the Time-based Recommender Approach for Lecture Materials (TBRA) [4], is based on time-dependent item similarities for the recommendation of study materials. The actual algorithm of presenting similar items has been adopted in this work to fit the recommender's goal and the evaluation approach. The fourth algorithm is, besides the SLR also a novel one. It generates personalized learning paths based on the activities of classmates and the previous interactions of the concerned learner [10]. The next items on the predicted learning path are, therefore, considered as Top-N recommendations.

For training and testing, we used activity data that we collected in a particular face-to-face university course with 99 students. The self-designed learning web app gave access to the course materials which comprised 1,006 learning objects grouped into 106 learning units (for more details see [8]). Thereby, a single learning object has a typical learning time

of, at the most, five minutes. A learning unit groups ten learning object (LO) items on average. We collected 44,421 xAPI statements which represent the item accesses of the 99 students. Instead of a traditional n-fold cross-validation, we used an extension of the "increasing time-window" cross-validation of Campos et al. [2] and a new measurement value, the timeliness [9], that presents the average timespan when a recommended relevant item has been accessed after its recommendation. In contrast to precision and recall, the timeliness measure must be as low as possible.

In the context of all evaluated recommender systems, the Smart Learning Recommender performs best on average regarding precision. Precision is the fraction of relevant items among the items of the Top-N list. Figure 1 visualizes the precision and timeliness of all evaluated approaches – each given in the best setting for the Top-3 recommendations for the university course. As seen on the precision chart on a weekly basis, the SLR (green line) is more scattered than the Learning Path algorithm that shows a worse but more stable trend. Regarding timeliness, the Learning Path algorithm still outperforms the Smart Learning Recommender. However, the Smart Learning Recommender also shows low timeliness values that are the second best on average which means that the recommendations are also very time accurate.

In a second experiment, we analyzed the effect of different learning patterns on the precision: Thereby, more precise recommendations have been obtained using only the most 33 most active learners, and not – as initially expected – the most successful learners (who completed the exercises most successfully on average). The SLR algorithm reaches a precision of 0.800 on average (compared to the previous value of 0.583 with all students). Of course, this is only an artificial setting, because the SLR cannot forecast the most active users at an early point in time and, more importantly, the recommender system should provide recommendations for all users – not only for the most active or most successful users. However, this indicates the potential of the algorithm, as the Smart Learning Recommender aims at recommending items for all users based on favorable patterns. These patterns might be, for instance, the activity patterns of the most active users. We also applied the SLR algorithm on activity data of two other courses – an optional online-

only course with 28 learners at another university and an adult education blended learning course that regularly reoccurs with eight craftsmen each. All courses show an effect of the cold-start phase with lower precision values at the beginning. On average, the two new courses reach almost similar high precision values of 0.818 (for the online-only course) and 0.815 (for the craftsmen's course). This confirms the findings of Verbert et al. [16] that the precision results of educational recommender systems highly depend on the dataset selection and, thus, implicitly on the course setting and the course participants.

5. LIMITATIONS & CONCLUSION

The Smart Learning Recommender introduces a relevance score that represents a numerical value indicating the need for learning (implicitly the knowledge gap) of a learner. This learning need is modeled through different factors and the resulting recommendations are presented in particular categories – such as "Exercises where you received weak results", "Things you might have forgotten" or "Please wrap-up these learning objects". The weights of the context factors are not static. The SLR shows that precision can be increased dramatically when modeling context factor weights over time. Thereby, the weights are determined on a weekly interval to understand the best composition. A dynamic weighting at every point in time allows for the generation of the most precise Top-N list. Due to the evaluation settings, time weights have only been analyzed at weekly intervals. We determined the most appropriate weights based on the most recent activities of the current user. Since the algorithm can also assign a weight of 0 to the factors, it is not counterproductive to consider as many factors as possible. However, other factors that additionally provide useful information about the need for learning still need to be investigated in the future.

The evaluations have been conducted in a simulation environment – with historical real-world data but in the absence of presenting the recommendations of all evaluated algorithms to real-world learners. Thus, the effect of the user interface and its usability have not been compared for the different approaches. Since these aspects have a huge impact on general user acceptance and user perception of the system as a whole, they require further experiments. While the different algorithms were evaluated with the help of a novel evaluation framework, the results can only indicate their various levels of appropriateness for the self-collected activity data. In general, the approaches should work similarly well on other datasets that offer the same kind of user, item and activity information. However, this has not yet been investigated.

ABSTRACT

We study content recommendation in an online learning environment for mathematics ($N=77$, 4th-5th grade student). We compare an expert teacher's recommendation to that of a neural network algorithm, implementing collaborative filtering ranking. We do so using a double-blind randomized controlled experiment. We find that when the difficulty of the teacher's sequence of recommendation was overall increasing, the teacher was superior to the algorithm regarding students' performance. Taken together, our findings indicate on how the algorithm and the expert teacher can benefit from each other.

Keywords

Content sequencing, neural network, collaborative filtering.

1. INTRODUCTION

Designing a learning process that is characterized by increasing task difficulty is a desired goal, for keeping learners challenged, motivated and engaged. Meeting this goal is also a matter of personalization. In some contexts of computer-based learning—e.g., in intelligent tutoring systems—such a personalization has been in practice for many years [1], [2]. In other e-learning settings, as well as in traditional classrooms, this is still a great challenge.

Personalization requires tailoring future content, based on past engagement with materials, and based on the difficulty of the materials. One of the most common approaches to do so is collaborative filtering [3]. We implement a novel adaptation of collaborative filtering, by ranking questions in order of their subjective "difficulty" to the student, with the latter defined based on different aspects of similar students' behavior while engaging with past questions. This method has proven superiority over other personalization algorithms [4]. Following that, we ask whether an expert teacher can do the same.

Ben Levy, Arnon HersHKovitz, Odelia Tzayada, Orit Ezra, Avi Segal, Kobi Gal, Anat Cohen and Michal Tabach "Teacher vs. algorithm double-blind experiment of content sequencing in mathematics" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 603 - 606

In order to conduct a fair comparison between human and computer recommendations, we used a double-blind randomized controlled study (RCT). RCTs have been underused in educational research [5]. Despite a recent boom in its use in computer-based educational settings [6], conducting double-blind RCTs in authentic classroom environments is still a rarely-met challenge.

2. METHODS

2.1 Population

Participants were 77 students in 4th-5th grades from a public school in a metropolitan area in Israel, 2 classes in each grade-level. In 4th-grade, there were 22 boys, 24 girls; in 5th-grade – 12 boys, 19 girls.

The expert teacher (third author) teaches mathematics in that school. She has 18 years of experience in teaching and about a decade of experience in incorporating technology in classroom. She is also well-familiar with the learning environment used here.

2.2 The Learning Environment System

We used a commercial online learning environment which includes game-based applets for K-12 school mathematics (per the request of the company, we do not mention its name). Each applet—consisting of a few problems that each allows multiple attempts—is aimed at a specific sub-content, usually focusing on a specific skill (e.g., identify fractions, make fractions, name fractions, compare fractions, etc.). Applets usually require some interaction from the learner (e.g., dragging and dropping visual elements) and give them feedback upon submitting a solution. We focus on the topic of fractions.

2.3 Data, Definition of Difficulty

We computed the absolute measure of difficulty for each applet based on historic data collected from students using the online learning environment. As each student can interact more than once with each applet, we used only the first attempt of each student with each applet. After preprocessing and cleansing of the data, each student-applet interaction contains the following tuple: <student id, applet id, score, start time, time spent on applet>. This dataset includes 563,735 rows, documenting 15,000 Israeli students who used 978 applets during 9/17-6/18.

For calculating the absolute difficulty of the applets used for our intervention, we sorted them based on their average score (according to the historic data), and used average time spent as a tiebreaker. Based on this ranking, we then divided the applets to

three equally-sized groups: levels 1 (easiest) to level 3 (most difficult). We did so for each grade-level separately.

2.4 Research Process

Data collection was done during December 2018-January 2019.

2.4.1 Partition to Research Groups

Partition to Algorithm/Teacher groups was based on a pen-and-pencil pre-test scores. Students were ordered by their score, and were assigned to Algorithm/Teacher groups, alternately.

2.4.2 Phase I Data Collection (Baseline)

During phase I, which served as a baseline data collection, all students of the same grade-level were assigned with the same set of 10 applets, in the same order. These applets were chosen by the expert teacher, based on the class syllabus. The students worked individually at the school's computer lab, with the teacher and part of the research team present but not intervening or helping them at any point. Students had about 90 minutes to complete the full set, and most students indeed did so; those who did not finish on time, came to the lab at a later time to complete the set.

The Teacher and Algorithm groups demonstrated similar behavior in Phase I activity, when measuring percentage of problems correctly answered on the first complete run of the applet and the time spent on the first complete run of the applet (see Table 1).

Table 1. Comparing the research groups' activity in Phase I

Grade	Group	Mean (SD) % Corr. Prob.	Mean (SD) Time Spent
4	Algo. (N=21)	0.76 (0.15)	210.47 (48.60)
	Teacher (N=25)	0.74 (0.20)	235.26 (94.33)
t-value		t(44)=0.45 [‡]	t(37.12)=1.15 [‡]
5	Algo. (N=15)	0.79 (0.22)	149.20 (41.50)
	Teacher (N=16)	0.88 (0.17)	142.36 (33.73)
t-value		t(29)=1.21 [‡]	t(29)=0.51 [‡]

[†] Levene's Test was significant [‡] Not significant

2.4.3 Constructing the Recommendations

Log files from Phase I were collected, preprocessed and analyzed. The performance of the students in Phase I served as input to the algorithm and teacher for selecting the applets for phase II. Both the computer and the teacher were given the same pool of pre-chosen applets (12 for grade 4, 20 for grade 5) from which they could assign 10 applets for Phase II. This set was focused on continuing learning and practicing fractions.

Both the teacher and the algorithm produced their recommendations for the full cohort of the participants. In order to ensure the teacher's "blindness", she was not allowed—at any stage of the experiment (in-class activities, report-examining, or recommendation-making)—to connect students with their system id; she was also not involved in the pre/post-test writing or grading.

Algorithm's Recommendation. We base our personalized recommendation on the NCFR algorithm output (Section 3.2) and then adapt it to our Phase II pool of applets. For each student, we place a sliding window in the middle of her or his ranking, and move this window one applet towards the less/more difficult applets, according to the their Phase I performance (one step for each SD below/above average of their grade-level, respectively).

Teacher's Recommendation. The teacher was presented with a table summarizing score and time spent for each student on each applet. Examining it, she decided to divide the students (in each

grade-level) to three level-groups ("weak", "intermediate", "strong"), and to assign a different sequence of 10 applets to each.

2.4.4 Phase II Data Collection (Intervention)

Each student was assigned with the applets they were recommended with, in accordance with their research group. Working conditions for students were the same as in Phase I.

2.4.5 Post-test

A few days after Phase II, the students took a pen-and-paper post-test on the material covered by Phase II. We observed no differences in post-test scores between the two groups. In grade 4, the average score (on a scale of 0-26) for the Algorithm group was 18.48 (SD=6.82) and for the Teacher group – 18.28 (SD=6.42), with t(44)=0.1, at p=0.92. In grade 5 (on a scale of 0-25), the average score for the Algorithm group was 17.00 (SD=7.52) and for the Teacher group – 18.06 (SD=6.27), with t(29)=0.43, at p=0.67.

3. RECOMMENDATION ALGORITHM

3.1 Problem Definition

In this section we define the *relative* measure of difficulty used by the algorithm to personalize applets to students. We consider an e-learning setting with a group of students S and a set of questions Q . The "difficulty ranking problem" includes a target student $s_i \in S$, and a set of questions $T_i \subset Q$, for which the algorithm must predict a difficulty ranking over T_i .

The input to the problem includes: (1) A set of students S ; (2) A set of questions Q ; (3) For each student $s_j \in S$, a partial ranking by difficulty over a set of questions $H_j \subset Q$. We assume a personal difficulty ranking over questions for each student. We compute the personal difficulty ranking by ranking questions according to students' first attempt score, breaking ties by time spent.

For every student $s_j \in S$ there are two disjoint subsets $H_j, T_j \subset Q$, where the difficulty ranking of s_j over H_j is known. For a target student $s_i \in S$, H_i represents the set of questions that the target student s_i has already answered (i.e., student's history), while T_i is the set of questions for which a difficulty ranking is needed (i.e., target questions). The task is to leverage the known rankings of all students s_j over H_j in order to compute the required difficulty ranking over T_i for student s_i .

In order to preserve the temporal order of events, we split the data to train and test sets; for each student, we sort his/her interactions by start time, then split the sorted interactions by taking the first 70% of the interactions as the train set and the remaining 30% of interactions as the testing test set.

3.2 Neural Collaborative Filtering Ranking

Our Neural Collaborative Filtering Ranking (NCFR) approach is a hybrid model based on two different fields: collaborative filtering and information retrieval. We apply the multi-layer neural network representation detailed in [7] to our domain. Figure 1 shows the network architecture, where the input is two one-hot encoded vectors that index student-question identity. These vectors are fed into two separate, fully connected embedding layers that output dense vectors which are a latent representation for the student and question (similar to latent factor models in collaborative filtering). The dense vectors are concatenated and fed into a multi-layer, fully connected neural architecture, mapping the latent vectors to a difficulty prediction score that depends on both student and question. The final output layer is the predicted difficulty score \hat{d} .

The training process of our model, Learning to Rank (LTR), is adapted from similar tasks in information retrieval [8]. Our network optimizes a LTR pairwise loss function, predicting the subjective difficulty of one question over the other for each given student. A forward pass of the network computes the probability that question q_i is more difficult than question q_j for student s . We separately predict the difficulty score $\hat{d}(s, q_i)$ and $\hat{d}(s, q_j)$, using the network. The probability that question q_i is harder than question q_j for student s is: $\hat{y}(s, q_i, q_j) = \sigma(\hat{d}(s, q_i) - \hat{d}(s, q_j))$.

Where σ is a *sigmoid function*. For example, when the score for q_j and q_i is the same, the model is fully agnostic (each question is harder with probability 0.5).

The objective function to minimize for NCFR is the *binary-cross-entropy*, and its optimization can be done by performing stochastic gradient descent (SGD):

$$L = -(I(s, q_i, q_j) * \log \hat{y}(s, q_i, q_j) + (1 - I(s, q_i, q_j)) * \log(1 - \hat{y}(s, q_i, q_j)))$$

Where $I(s, q_i, q_j)$ (i.e., the indicator function) is 1 when question q_i is more difficult than question q_j for student s , and 0 otherwise.

We use Copeland's pairwise aggregation method [9] to convert the pairwise difficulty predictions for all students to a ranking over the target question set, using the same procedure as Segal et al. [4].

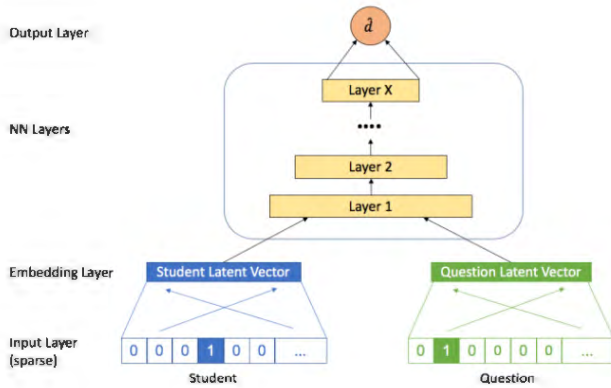

Figure 1. Neural network architecture (adapted from [7])

4. FINDINGS

4.1 Overall Difficulty in Phase II

We examine the difficulty of the teacher's assignment to "weak", "intermediate" and "strong" group of students based on the data collected in Phase I. Calculating averages of the teacher's recommended applets for each group, we get an increasing value from the "weak" to the "intermediate" and from the "intermediate" to the "strong" groups. (As we compare averages of 10 numbers in each case, we do not run statistical analyses for significance.) This indicates an overall **alignment between the teacher's evaluations of the applets' difficulty level and their absolute difficulty measure**. Findings are summarized in Table 2.

Table 2. Average difficulty of teacher's group-based sequences

Grade	"Weak"	"Intermediate"	"Strong"
4	1.9	2.1	2.4
5	1.4	1.8	2.5

We now compare between the teacher's and the algorithm's recommendations' difficulty for Phase II. We calculate for each student the average of difficulty across their 10 recommended

applets, then calculate the average across students. Overall, the **teacher, compared with the algorithm, recommended more difficult applets**. These differences are statistically significant, although denote a small effect size (see Table 3).

Table 3. Comparing difficulty of recommendations

Grade	Avg. (SD) Teacher	Avg. (SD) Algorithm	Paired t-test	Effect Size [†]
4 (N=46)	2.17 (0.21)	1.96 (0.11)	9.32***	0.05
5 (N=31)	2.02 (0.44)	1.77 (0.18)	3.84**	0.13

** p<0.01, *** p<0.001, [†] Cohen's d

4.2 Difficulty along Phase II

For comparing between recommended sequences that may differ from each other by their applets and/or by the applets' order, we refer to each student's 10 ordered learning opportunities (LOs). This approach has been repeatedly taken in the EDM community.

We examine the difficulty of the LOs by averaging difficulty for each LO separately (across students), comparing between the teacher's and the algorithm's recommendations. For grade 4, the algorithm's recommendation is characterized by an overall increased difficulty level along the LOs, while the teacher's recommendation has an overall opposite trend. This is supported by calculations of the linear trend for both vectors, with $m=0.13$ for the algorithm, and $m=-0.13$ for the teacher.

For grade 5, we observe an overall increasing trend in both cases; linear trend calculations result with $m=0.15$ and $m=0.07$ for the algorithm and the teacher, respectively. See Figure 2.

Figure 2. Phase II Recommendations' difficulty (grade 4 – top, grade 5 - bottom), teacher (dark) and algorithm (light)

We also evaluate level of agreement between the teacher's and the algorithm's actual recommendations, using AP correlation [10], which measures similarity between two different orders; we apply this measure for the overlapping of each student's two recommendation sets. For grade 4, the average AP correlation is 0.42 (SD=0.12, N=46). We also note that the average size of the overlapping subset is 6.22 (SD=0.87). For grade 5, the average AP correlation is 0.75 (SD=0.22, N=31), with an average overlapping

subset size of 5.19 (SD=0.79). These are in line with the abovementioned findings: where both recommendations demonstrate increasingly difficulty (grade 5), we observe high alignment between the recommended sets, while where there are opposite trends (grade 4), the level of alignment is much lower.

4.3 Students' Actual Behavior

For each LO, we calculate the average score across each research group. As may be seen in Figure 3, in grade 4 there is no clear advantage to either the teacher (N=25) or the algorithm (N=21) groups, while in grade 5, there is an overall advantage for the teacher group (N=16) over the algorithm group (N=15). Considering the findings reported in the previous section, we may infer that **when the algorithm's and the teacher's recommendations align – the teacher has an advantage over the algorithm; in contrary, where the algorithm's and the teacher's recommendations do not align – neither the teacher nor the algorithm demonstrates an advantage over the other.** Note that due to small sample sizes, we do not run statistical analyses here.

Figure 3. Phase II scores for grades 4 (top), 5 (bottom), comparing teacher (solid) and algorithm (dashed) groups

5. DISCUSSION

In this study, we compared between difficulty level of personalized recommendations of an expert teacher and a novel algorithm, in the context of elementary school mathematics. We find that the teacher had overall recommended more difficult applets than the algorithm. However, students in the teacher group did not achieve lower than their peers in the algorithm group. Therefore, we may suggest an improvement to the algorithm—and educational software at large—i.e., enabling more difficult tasks, in order to maximize students' engagement and learning within their zone of proximal development [11].

Additionally, we show that the teacher did not always recommend an increasingly difficult sequence of applets, while the algorithm—by its very nature—did so indeed. When such a trend was observed in the teacher's recommendations (grade 5), the teacher demonstrated superiority over the algorithm regarding students' performance during intervention (Phase II). This may be a result of the teacher considering additional parameters to the ones considered by the algorithm; for example, familiarity with the topics and with the content of the applets (it is our plan to interview the teacher regarding her thought process while personalizing applets). This, again, may be taken as a point of improvement to the algorithm. On the other hand, this finding highlights the superiority of objective, data-based difficulty level of the applets, which

probably incorporates—"unconsciously", though this term is not appropriate for a machine—other applet characteristics, such as animation, interactivity, narrative, etc. Taken together, these findings indicate on how the algorithm can benefit from the expert teacher's experience, and vice versa.

The differences in the teacher's recommendations for grade 4 and 5 could be explained by the different pool sizes from which she could choose applets for the intervention phase (the pool for grade 4 was smaller than that of grade 5). We plan on replicating this study with larger pools, as well as with other grade-levels and more topics.

ABSTRACT

The increasing capabilities of intelligent tutoring systems (ITS) that collect student interaction data while learning mathematics at the middle school level have enabled researchers in educational data mining (EDM) to develop models that predict student career choice. Current research focuses on feature selection techniques that provide essential features in predicting the target variable. However, the factors that affect the prediction performance of an algorithm at a sample level could be studied in depth as they influence the overall performance of an algorithm. In this study, we analyze the influence of various attributes collected by the ASSISTments online learning platform on the performance of machine learning algorithms in predicting student career fields. Initially, we adopt a feature selection technique based on correlation, ID-ness, stability, and Missing values to determine useful attributes and then apply machine learning algorithms to classify student field. The trained models will be used to extract the supporting and contradicting attributes that influence the prediction performance of an algorithm. The results showed that the affect state confused played a significant role in supporting Non-STEM prediction, and boredom played a substantial role in contradicting STEM predictions while gaming the system influences both STEM and Non-STEM predictions. This proposed study facilitates researches in the field of EDM with factors that influence the development of efficient models in predicting STEM and Non-STEM careers.

STEM Career, Factor Analysis, Feature Selection, Educational Data Mining, Affect State.

1. INTRODUCTION

Investigating factors that influence student interest in STEM fields at middle school level supports researchers to develop methods that help to focus on areas that empowers their interest in STEM as a career choice. The increasing adaptation of learning technologies like Intelligent tutoring services (ITS) and Massive open online courses (MOOC) at school level supports researches in the field of educational data mining (EDM) to predict student

career choices based on their interaction [6]. With the advancement in the design and capabilities of these systems to collect student interaction data, affect data and knowledge data, different models were developed to understand and predict factors that influence student interest in the STEM field [7]. Social cognitive and career theory (SCCT) show evidence that learning and knowledge pattern at a younger age influences student STEM career [5]. The student interest in mathematics during middle and high school years improve their self-efficacy and performance which can be an influential factor for STEM major enrollment [6,10]. Affective engagement and behavioral models developed earlier showed relationship with choice of majors and college attendance.

An earlier study on predicting student career choice from interaction and affect state data showed a negligible effect of affect state in predicting student career [11]. This study extracts features related to knowledge states based on student problem-solving abilities and skills that were used to predict their fields. Although this study discusses the influence of various predictors on predicting student knowledge states, their approach is to average samples in student log instead of utilizing available comprehensive data. These predictors were then subject to feature engineering and feature selection techniques to incorporate them in algorithm training and testing that improves prediction performance. However, even with the careful selection of predictors following reliable methods the performance of trained algorithms in predicting new student samples is not high. In our study, we incorporate feature engineering and feature selection methods to train and test multiple machine learning algorithms and analyze predictors that support and contradict prediction made by these algorithms. This type of factor analysis will develop an understanding of predictors on classification algorithms.

In this study, we adopt a feature selection technique based on stability, ID-ness, and correlation (Pearson) measures of attributes [4]. We developed three categories (Safe, Moderate and Unsafe) of features based on these measures. Features that fall in the safe and moderate categories were then used to evaluate different machine learning algorithms. The highly supporting and contradicting features for each sample in the dataset were identified based on neighboring attribute weights that utilizes correlation as an identification factor. The local linear relation between attributes is highly influential in prediction compared to the non-linear global relationship [2]. Analysis of features that support and contradict predictions related to STEM, Non-STEM predictions facilitates to understand the importance of each feature on individual class prediction.

2. DATASET

This study adopts the ASSISTments dataset provided during Educational Data Mining (EDM) competition in 2017. ASSISTments platform captured US middle school student interaction data from 2004 to 2007 school years [7,9]. This dataset consists of 1709 student's system interaction data. These students were requested to participate in a survey conducted to record post-high school career achievement. This survey provided the career choices of 591 students. In this, 466 students belong to Non-STEM field, and 125 students belong to STEM field.

3. METHODOLOGY

This study mainly focuses on three aspects; initially, we perform feature selection then evaluate machine learning models and extract predictors that support and contradict predictions. Figure 1. shows the complete methodology of this study.

3.1 Feature Selection

Feature selection technique based on correlation, stability, ID-ness and missing value of an attribute was adopted [4]. Correlation in this study considers the linear correlation between attribute and target column. The percentage of ID-ness implies the percentage of different values present in a column. For instance, an attribute with incremental values can have an ID-ness of 100%. Stability is the measure of constant values in an attribute. Stability is zero if there are no similar values where stability is 100 percent if all the values are the same in an attribute. Missing value measure is the percentage of values missing in a attribute. We categorized these attributes into three categories based on the measures mentioned above.

The unsafe category consists of attributes that have more than 70% missing values, or the column is an ID column which is decided based on the ID-ness value, or stability more significant than 90 percent or correlation less than 0.0001 percent or higher than 95 percent. This study removes the attributes from the dataset as they diminish the performance of algorithms. The moderate category consists of attributes that have an ID-ness value of 85%, or correlation less than 0.01%, or correlation more significant than 40%. Attributes that fall in this category will have minimal impact on the predictions. This study included these attributes for analysis. This category consists of attributes that have low ID-ness, the correlation between 0.01 and 40 %, no missing values and stability less than 90%. Attributes in this category profoundly positively impact prediction.

3.2 Model Validation

We adopt the RapidMiner data science platform to train and test chosen predictive models [3]. In this study, we evaluated five machine learning models that differ based on their principles. We chose gradient boosted tree (GBT), Deep neural network (DL), AutoMLP(Multilayer perceptron) random forest (RF) and logistic regression (LR). We discuss model hyperparameters in below

subsection. All the algorithms were evaluated using five-fold cross-validation method on features selected from the above method.

3.2.1 Models and Hyperparameters

1. *Gradient Boosted Tree*: Gradient boosted tree algorithm is a sequential learning algorithm in which a subsequent tree learns from the weak predictors of a previously built tree. The tree adopted in this study has a maximum of 20 trees, maximal tree depth of 20 and a learning rate of 0.1.
2. *Random Forest*: A random forest is an algorithm that works based on ensemble learning principle. This algorithm can combine different models developed based on the bagging method. We obtained optimal settings for this algorithm with a maximum of 100 trees and a maximal depth of 10 per tree.
3. *Logistic Regression*: Logistic regression method is for classification problems as it predicts the probability of each class and classifies based on the probability values. We adopt the standard settings for this model.
4. *AutoMLP*: A multilayer perceptron is a feed-forward neural network that consists of multiple hidden layers in training a neural network. The AutoMLP algorithm can set the optimal learning rate and hidden layers during training. This algorithm works on stochastic optimization and genetic algorithms. This algorithm trains small ensemble methods in parallel with different hyperparameter settings like hidden units and learning rate which are validated to find the best setting.
5. *Deep Neural Network*: A deep neural network is an algorithm that can work with different activation layers, learning rates and optimizers. In this study, we adopt a four-layer (input, hidden_1, hidden_2, and output) fully connected deep learning network that has 250 hidden units in each layer. We set the learning rate at 1.0E-5 and use rectifier activation function. The regularization parameters were auto-adjusted based on the training performance of the algorithm

3.3 Confidence Calculation

In this study, we adopted a confidence-based method that calculates the confidence value ranges between 0 and 1 of student prediction based on the actual and predicted label over all their samples. We extract the cross-validation predictions of each algorithm to calculate the confidence of each student and then label their choice of field as STEM or Non-STEM. If the student prediction confidence over all samples is greater than 50 percent, then the prediction is the same as the actual label. If the student prediction confidence is less than 50 percent, then the prediction is opposite to the actual label of the student.

Figure 1: Architectural flow of student career prediction

3.4 Predictor Explanation

This purpose of this study is to understand the factors that influence STEM and Non-STEM predictions. For this purpose, we utilize "explain predictor" operator from RapidMiner to understand the purpose as mentioned above. This method creates neighboring data points for each sample in a dataset and calculates local correlation values to identify the weights of each attribute. The predictors that support and contradict are classified based on the local correlations and weights calculated for each attribute for every sample. The words "supporting" and "contradicting" refer only to the predicted value which might be a accurate or inaccurate prediction. The linear relationship between attribute and prediction locally is highly influential; even the attributes are nonlinear globally.

4. RESULTS

4.1 Cross Validation Performance

This study adopts a cross-validation method to evaluate five machine learning algorithms. Table 1 below shows the cross-validation performance of predictive models built on safe and moderate features categorized by feature selection method. Gradient boosted tree that learns sequentially from weak learners performed better compared to other complex models like deep learning. The performance (AUC, Kappa, and RMSE) of predictive models evaluated on with safe and moderate features show a slight improvement compared to the performance of models based on High impact features.

Table 1: Cross Validation performance of machine learning models on feature selected data with safe and moderate features.

Algorithm	AUC	Accuracy (%)	Kappa	RMSE
Gradient Boosted Tree	0.999	98.83	0.964	0.116+/- 0.002
Deep Learning	0.674	58.19	0.150	0.388 +/- 0.001
AutoMLP	0.623	79.89	0.048	0.396 +/- 0.002
Random Forest	0.635	79.63	0.004	0.398 +/- 0.000
Logistic Regression	0.588	79.58	0	0.400 +/- 0.000

The confusion matrices for STEM and Non-STEM predictions for 591 students were developed based on a confidence cutoff value at 0.5. The below-mentioned table 2 are confusion matrices with Recall and precision scores calculated. As observed earlier GBT and DL does better with high class precision and recall values compared to AutoMLP, RF and LR which were unable to predict STEM classes.

4.2 Explain Predictions

The main focus of this study is to understand the predictions made by the adopted machine learning algorithms. For this purpose, we extract all the supporting and contradicting attributes and present

top six in below Tables 3 and 4 for both accurate and inaccurate predictions. These supporting and contradicting algorithms were classified based on the local Pearson correlation values obtained by calculating the correlation between the attribute and prediction made. One should be careful in interpreting support and contradict predictors. For instance, a supporting predictor for a sample with accurate prediction (Actual Label = Predicted Label) means that this predictor acted positively on predicting actual label whereas a supporting predictor for inaccurate prediction (Actual Label \neq Predicted Label) means that this predictor acted negatively for this prediction. This explanation is similar for contradicting predictors, where the contradicting predictor has negative effect on accurate predictions and positive effect on inaccurate predictions.

Table 2: The below tables shows the confusion matrices with their class recall and precision values for all five machine learning algorithms adopted in this study.

Gradient Boosted Tree	True ST	True NS	Class Precision (%)

5. DISCUSSION

This study explores the importance of feature selection and investigates the local linear correlation of predictors on predictions. Affect states, knowledge traces, and clickstream records were studied extensively to understand their impact on model predictions. We observe that the "NumActions" has a high impact on overall accurate predictions of GBT but adversely effects Deep Learning algorithm, this might be due to the differences in the statistical background of algorithms and their regularizations functions. Now in case of accurate STEM prediction made by GBT model, attempts and clickstream records support the prediction whereas affect state boredom and disengaged behavior off-task acts negatively on accurate STEM predictions. Affect state confused has a high positive influence in predicting Non-STEM class and disengaged behavior gaming also supports an accurate prediction of this class. Affects states impact on deep learning algorithm seems to be negligible as most of the predictions depend on knowledge states and clickstream records. Gaming the system has negative impact on STEM career prediction and overall predictions. A previous study by San Pedro et al. also found this relationship between gaming the system and Non-Stem students during their major selection [9]. One reason for the pattern mentioned above might be related to students turning from boredom to off-task which negatively impacts STEM choice [1].

Previous studies suggested a high correlation between carelessness and STEM students [6,8]. In this study, the impact of Average carelessness attribute available in this dataset is investigated to check the model performance based on its presence and absence. With the inclusion of average carelessness, the performance metrics of the GBT model increased. From the predictor explanation, we observe that the Average carelessness has a high impact on accurate STEM predictions. This predictor importance is in line with previous studies that proved the importance of carelessness in case of students opting STEM fields [6,10]. One limitation of this study is related to the use of clickstream data which depends on multiple factors like time spent on the system, the number of questions

answered which may vary when considering different sets of students that work on the platform during different periods. Another limitation is the generalizability of this study as the dataset analyzed is from a single platform (ASSISTments), and the predictor relevance are model specific.

In our future work, we focus on developing feature selection techniques based on the useful predictors and develop models that efficiently and effectively predict their choice based on their middle school year data.

A Methodology for Student Video Interaction Patterns Analysis and Classification

Boniface Mbouzaio

Ian Shrier
McGill University

ABSTRACT

Massive open on-line courses (MOOCs) often rely on video as the prime choice of media content. Given their importance, it is no surprise that many studies that focus on the way students engage with the videos within the MOOC emerged in recent years. A methodology is introduced for the detailed analysis of student video watching patterns and compared with a prevailing approach. The method encodes video interaction sequences in a vector space model that defines distance measures between them. A pattern is defined as a centroid of sequences. We apply the method and conduct a study of how students interact with videos by analyzing interaction patterns across different videos. Within this method, the analysis of the influence of video on patterns is framed as a classification task based on Support Vector Machine (SVM), Boosted Tree (GBM) and nearest neighbour approaches. The results reveal there is a significant difference in the patterns of interaction across videos. It demonstrates the usefulness of the methodology in comparison with a simpler and common approach.

Keywords

MOOC, video watching event traces, analytics, clickstream, video feature, student traces, video event.

1. INTRODUCTION

In contemporary versions of MOOCs, videos play a significant role in the delivery of the course content. Videos often represent the main channel for teaching in MOOCs, and possibly for distance learning environments in general (see for eg.[3, 9]). Video interaction events such as *play*, *pause*, *seek*, and *stop*, characterize how a student listened to a video.

While we find a substantial amount of research to determine factors relating to videos that impact student engagement and learning efficiency, we still find relatively few studies on how students interact with videos themselves, beyond simple aggregations of video watching events. This study adds a contribution to fill this gap by introducing a methodology

to study such patterns based on sequences, and by applying it to uncover differences in interaction patterns across videos. To test this methodology, we investigate whether videos induce student interaction patterns. In other words, could a specific video has its own “signature” in terms of video watching pattern?

2. RELATED WORK

We first review the work that relates to the methods of analyzing student logs of video watching sessions, and in particular the basics of the feature based video analysis.

2.1 Student interaction patterns

Video interactions can be obtained from logged events, and we can distinguish between two approaches of analyzing such logs, namely those that preserve sequential information of interaction sessions, and those that extract features from events and eliminate time, or ordering information.

For example, characterizing video interactions in terms of total watch time, total pause duration, percent completion, video speed, etc., obviates the order or the timing of the corresponding events. The alternative approach is to characterize a video interaction as a sequence of events, or activities [4, 11]. The former characterization, we refer to as *feature-based*, retains numeric features or Boolean factors that can be used to predict variables of interest such as engagement, learning style, etc. In the later characterization, *sequence-based*, interactions are time-ordered sequences between which we can measure distances. Our approach falls into this second category and will be exposed later.

An instance of the feature-based approach that extracts information from video interaction sessions is the highly cited study of Guo et al. [5]. Their study is conducted over a very large sample of MOOCs and student sessions. They found that multiple factors associated with videos can affect student engagement, as measured by the length of watching time and the students’ willingness to complete an assessment activity.

Another interesting finding of Guo et al. [5] is that tutorials are often watched multiple times and for longer periods than lectures. This finding hints that some videos can induce a watching pattern.

In a similar vein, Bhat et al. [2] found that slight changes in how the teacher is depicted in a video can influence engage-

Boniface Mbouzaio, Michel Desmarais and Ian Shrier "A Methodology for Student Video Interaction Patterns Analysis and Classification" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 611 - 614

ment in terms of the proportion of video watched, which is another instance of a feature-based analysis.

Moving on to the sequence-based interaction analysis, the Sinha et al. [11] study is particularly relevant and original. Instead of using raw events such as *pause* and *play*, they also look at pairs and n-tuples of events. They develop an n-gram based encoding of video watching events and use subsequences of events in addition to individual events. They attempt to use levels of n-gram interaction and predict engagement, identify arousal states, and likeliness of dropout. Their approach reaches a good level of prediction accuracy with a Kappa score that ranges between 0.5 and 0.9 for the different predictions. A similar approach has also been applied to problem solving student log data [10].

Other instances of sequence-based interaction analysis have been conducted over data from student usage logs of different learning applications [4, 7, 6]. These approaches use a distance measure, generally the minimum edit distance, or Levenshtein distance, to cluster sessions. The sequences of events are transformed into sessions of activities represented by vectors. Each unit of the vector represents a time duration and corresponds to an activity. The clustering of such vectors yields a synthetic view of the different types of sessions.

The current approach is inspired from the sequence-based interaction approaches and uses a distance measure between watching sessions. However, the similarity among sessions is not based on the Levenshtein distance, or edit-distance. Instead, it defines a vector space model. Furthermore, a class label is represented by a point in that space corresponding to the prototypical sequence of the class label. We introduce later the means by which a prototypical sequence of interactions can be defined and demonstrate how it can identify the watching pattern of each specific video. Before, we describe the basics of the feature based video encoding.

2.2 Feature based video encoding

Our approach is compared to the feature based encoding approach. As mentioned, this is a common approach to detect unique patterns and predict factors of interest such as student engagement level, in-video dropout, and course completion or dropout [11]. Below is a summary of the six video watching features we track.

1. **Video length:** Student interaction can be affected by the length of the video. Some studies have shown that shorter videos are much more engaging [5], thus one of the characteristics of student video interaction is the length of the video.
2. **Length of time that student played the video:** This is the total amount of time that the student play a video, including if the student plays the same section of the video more than once. In general, this feature is expressed as a percentage of video play time compared to the video length.
3. **Number of times that the student paused and where the student paused in the video:** Frequent or long pauses may reveal aspects of a video, such as

its level of difficulty, as has been found in some studies [8].

4. **Number of times that the student seeks the video backward:** The backward seeks for a student show how replaying some part of a video is important or the importance of those video sections in the process of student learning.
5. **Number of times that the student seeks video forward:** The forward seek indicates the level of disengagement of the student by skipping sections of the video. For Li et al. [8] either infrequent watching or skipping large sections of the video suggested that the video was perceived to be of a higher level of difficulty.
6. **Number of times the student stopped the video:** In general, the stop event occurs at the end of the video though the student can stop the video at any time.

3. METHODOLOGY TO ENCODE AND CLASSIFY VIDEO INTERACTIONS

In this section, we introduce the method used to encode and classify video interactions that allows a comparison of encoded sequences in terms of distance. Akin to other studies [1, 11, 4], this distance-based approach lends itself to clustering of sequences, but our aim differs from these studies in that we wish to use a labelled data approach. In this study, we will use the videos as the target labels of interest to demonstrate the methodology. The proposed encoding allows a characterization of a video based on a set of instances of watching interaction sequences.

3.1 Video interaction encoding

The general principle is to characterize the video by a prototypical representation, which we will name the *video centroid*, and by which a distance from a student's video interaction sequence can be computed. This will allow us to compute a distance from a student interaction sequence to each of the different video.

In order to achieve such representation, we expand the original sequence of single events by using a vector representation of events. An event is defined as a vector of 5 types of events. For example, a sequence of four events, $s = \{(\text{play})_1, (\text{play})_2, (\text{pause})_3, (\text{stop})_4\}$ out of a set of six event types that also includes *seek forward/backward* events, is represented as:

$$s = [\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3, \mathbf{e}_4] = \begin{matrix} & \begin{matrix} play & play & pause & stop \end{matrix} \\ \begin{matrix} play \\ pause \\ seek\ backward \\ seek\ forward \\ stop \end{matrix} & \begin{pmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \end{matrix}$$

Now, assuming we have a set of n sequences, \mathbf{s} , where each sequence is composed of m events ($|\mathbf{s}| = n$ and $|s| = m$), we define the centroid of this set as $\bar{\mathbf{s}} = [\bar{\mathbf{e}}_1, \bar{\mathbf{e}}_2, \dots, \bar{\mathbf{e}}_m]$ where $\bar{\mathbf{e}}_i$ is defined as

$$\bar{\mathbf{e}}_i = \begin{bmatrix} \sum_{j=1}^n e_{i,1,j}/n \\ \vdots \\ \sum_{j=1}^n e_{i,5,j}/n \end{bmatrix}$$

Figure 1: Representation student i 's interaction with a video of length of n seconds

1	2	3	4	5	6	7	8	9	...	n	video length
Pl	Pl	Pl	Pl	$Pa.5$	
.	.	.	.	Pl	Pl	Pl	Pl	$Se.-6$.	.	
.	.	.	Pl	Pl	Pl	$Se.3$	
.	Pl	Pl

1	1	1	2	2	2	1	1	0	...	1	play
0	0	0	0	1	0	0	0	0	...	0	pause
0	0	0	0	0	0	0	0	1	...	0	seek-backward
0	0	0	0	0	0	1	0	0	...	0	seek-forward
0	0	0	0	0	0	0	0	0	...	0	stop

A more complex example of a student i sequence of interaction with a video of length n seconds can be represented as in figure 1. In this example, the student uses *seek* actions to navigate, and therefore some parts of the sequence contain more than a single *play* event at a given time.

3.2 Centroid based classification

The centroid of a set of sequences is defined as a prototypical sequence and represents a class. In the experiment below, this set will be the sequences of interactions of a video. Each event of that class sequence contains averages of the 5 types of events. This allows to define the distance between an individual sequence, s , and a prototypical sequence, \bar{s} , as the Euclidean (Frobenius) norm of the difference between the two matrices: $\|s - \bar{s}\|$, since both s and \bar{s} can be considered as matrices.

To determine the extent to which the prototypical sequence of each video is representative and discriminating, we can use SVM, Boosted Tree and a nearest-neighbour approach to classify sequences on the four same length videos, as explained below.

4. EXPERIMENTS

We apply the methodology described in the last section on the question of whether videos induce different patterns of interaction. The question is framed as a classification task: given a set of interaction sequences of a video, determine the corresponding video.

Our study uses the traces of an online course of McGill University in Montreal in the edX platform that had a substantial number of registered students (Table 1). The course Body101x was given by Professor Ian Shrier in the autumn 2015 and winter 2016. We have access to the traces of both sessions.

Session	autumn 2015
Nb. Students	30,640
Nb. videos	138 + 1 live
Nb. Students honor	10,424
Nb. Students passed	970

Table 1: Course and video information

While the whole course contains 139 videos, we retain 4 sets of 4 videos of them for this study, based on the criteria that in each set the duration of videos are the same (within 8 to 10 minutes). The choice of using a subset of same duration is meant to avoid a bias due to duration: since video duration can induce specific patterns and since duration can vary across the videos, selection of same duration videos avoids this potential bias.

For the purpose of comparing the proposed sequence-based approach with the simpler feature-based approach, we replicate the classification task using feature-based approach (section 3.2). The features are represented as a vector containing the mean proportion of each event: For each video, the events proportions of *pause*, *play*, etc., are computed. Classification of a given interaction sequence into one of the 4 videos is done using SVM, Boosted Tree and a nearest-neighbours approaches, akin to the sequence approach.

5. RESULTS

The results of the classification are shown in table 2. The methodology we used is compared with the features-based approach described above. The results show that the sequence-based approach is substantially better than the feature-based for classifying videos. They suggest that the sequence-based method of analyzing video traces yields more precise representations of interaction patterns than the feature-based, at least when applied to the task of characterizing interactions with different videos. This is demonstrated by a classification task, where video interactions are encoded in a vector space model and a given video is classified by SVM, Boosted Tree and a nearest-neighbour approaches, where centroids represent the classes, namely the videos.

6. CONCLUSION

The results show that the sequence-based method has the advantage of providing a more precise encoding of a set of individual student interactions into a "pattern" than the simpler aggregation of feature variables that is often used in studying student interaction traces with videos, or student traces in general. It allows the definition of labeled clusters, the video styles in our case, that contrasts with standard unlabeled clustering which requires the often difficult interpretation of the clusters.

7. LIMITATIONS

The conclusion that videos induce different interaction patterns among students is limited to a single course. While the number of videos in this course is substantial and the MOOC attracted a large number of students over two years, we cannot rule out that other factors than videos induced the difference in interaction patterns. However, we did rule out the possibility that this is linked to a presenter biased, by

Classifier: Approach:	SVM		Boosted Tree		Nearest Neighbour	
	Sequence	Feature	Sequence	Feature	Sequence	Feature
Accuracy	0.45	0.30	0.43	0.41	0.39	0.25

Table 2: Accuracy of tenfold cross validation runs of four videos of same length using feature-based approach and the proposed sequence-based method.

running the classification task over presenters, and the finding that the predictions are substantially lower than for the videos. Nevertheless, we did not go over all other possible covariates that could induce a bias.

To a lesser extent, the demonstration that the sequence-based method of characterizing interactions is more precise than the feature-based is also limited to the sample of this study. However, it is harder to find a reasonable explanation that a covariate is responsible for the higher accuracy of the sequence-based approach. We therefore consider this finding more reliable, albeit still requiring further investigation to bring greater confidence in the findings.

ABSTRACT

Automated learning systems allow educators to scale up their efficacy, while personalized systems retain the ability to customize to the individual student. A core issue in developing such adaptive learning systems is to understand how different items (e.g., math exercises) relate to one another, and to exploit this understanding to predict performance on an item. Data-driven approaches aim to discover latent concepts through embeddings that predict similarity between items, typically using only performance data or item data, but not both. While these embeddings are meant to uncover latent concepts (e.g., associativity in mathematics or chemistry), they are better construed as representing topics that reflect the similarity structure in performance or item features. One major difficulty is that embedded concepts may differ only in presentation and not in substance. For example, when learning about numbers, young children struggle with different representational formats (e.g., finger counts, Hindu-Arabic numeral) despite the underlying concept being the same (e.g., “3”). By incorporating item information that allows structured similarity comparison between an item’s content and representational format, we can begin to parse out what aspects lead to behavioral differences. Here we develop a deep learning framework for learning concept embeddings that integrates behavioral and item-features to better factorize embeddings into content and presentation. This allows us to fully represent the complexity of the items space, while still extracting scientifically-useful results from the analysis.

Keywords

education testing, item similarity, deep learning, concept discovery

1. INTRODUCTION

Personalized learning systems use student performance to assess their current knowledge in order to present appropri-

ate questions; understanding item similarity helps in this inference process [6]. When the goal is to predict performance, this similarity measure should most likely correspond to the abilities or skills the items are meant to test (e.g., whether a student knows multiplication or not). Data-driven discovery methods for similarity are needed for larger sets of items [1]. There are many ways to measure similarity [6], however all require that items be represented in the same feature space. This means that one of the most important decisions in computing similarity is the choice of input data, because it determines the meaning of the discovered similarity [7]. Having a rich input feature space which correctly corresponds with the intended application maximizes discovery of relevant relationships. For instance, if a user can struggle with either an item’s content or presentation, then features relevant for both are necessary to determine which impacts performance.

Importantly, raw features can be projected into a latent or embedded representational space. This is the common approach for topic modeling in text analysis [3], which finds latent ‘topic’ representations for documents and words. Typically these embeddings are discovered using either performance or item data, but not both. Using both types of data appropriately is challenging because the method of discovering the embeddings must respect the structural relationship between item features and performance data, and the structure in the item features themselves. To understand the similarity in educational concepts, we want to represent item similarity in terms of how the item features interact with performance data. This is because educational concepts refer to not just intrinsic aspects of the item, but the way that different learners interact with and represent them.

An example that illustrates the difficulty of discovering such embeddings in education is in number representations. Adults can easily switch between various representational formats of numbers (e.g., Hindu-Arabic numerals to mathematical concepts, finger counts to roman numerals, etc) to make assessments [8]. By contrast, young children struggle with some representational formats, which can greatly impact their ability to perform on an otherwise simple problem. This is similar to creating representations that respect the ‘style vs. content’ distinction [9], in that the latent representation must correspond to the structure that is hypothesized in the data.

Dominic Mussack, Rory Flemming, Paul Schrater and Pedro Cardoso-Leite "Discovering item similarity through deep learning: combining item features and user behavior." In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 615 - 618

The difficulties in estimating similarity are partly due to the complexity of item features. We demonstrate this using Mathemarmite (mathemarmite.lu), an educational game designed to teach children numeracy. Mathemarmite requires children to appropriately count using different representations (e.g., digits, fingers) (see figure 1). Each item requires selecting the right number of each ingredient to mix together, with the ingredient count represented in various ways. Trials are structured hierarchically, as a single “recipe” can include multiple representations at once with varying count. In other words, each item can have multiple “sub-items” that must be completed in any order for successful item completion. This produces an added complexity where any method we develop must deal with both variable number of features and permutation invariance [10]; the order of the items completed is arbitrary.

Figure 1: A standard trial in the educational game Mathemarmite. Children change the visuals of the monster (on the right) by correctly following recipes on the scroll. Ingredients from the shelf can be placed in the cauldron, with correct number of each ingredient shown on the recipe using various numeric representations (here tick marks and a die). Item features include the number of lines, line representation, and number of ingredients per line. Mathemarmite uses an adaptive difficulty system, to keep users engaged at their skill level.

Here we develop a deep learning approach towards discovering similarity in Mathemarmite. Our approach is similar to partial least squares [2], in that we find a directed latent space representation where item similarity is constrained based on similar performance. It is also similar to work by [11], who develop a dynamic key-value memory network (DKVMN) which learns a concept embedding for items, and models an evolving knowledge-state of a learner. A similar memory-augmented neural network approach in educational systems was used by [4]. These approaches use long short-term memory (LSTM) networks to compress a user’s history, along with attention-based mechanisms to compute similarity among items. We limit ourselves to a non-dynamic system, given the data size we are working with. Our approach focuses on user-independent concept space (see figure 2), attempting to find a similarity score across users.

Figure 2: Item features v_j and v_i are used to predict performance on item j by embedding them in a similarity space C . The similarity score c_{ij} is used along with performance on problem i to predict problem j . This constrains the similarity space to finding scores that are similar in terms of their impact on performance.

2. METHODS

2.1 Datasets

We present results using one simulated dataset and one collected educational game dataset (i.e., Mathemarmite). The Mathemarmite dataset is based on 4961 trials from 140 users (after cleaning to remove users with less than 5 trials and users who are not in the target demographic i.e., remove adults). The simulated dataset is constructed to mimic the structure of the Mathemarmite dataset, based on the assumptions of the similarity network (e.g., figure 2). That is, we generate 5 latent “concepts”, represented as 5 Gaussian spheres in concept space (each 5d), and sample item concepts from them. Items are then transformed to produce observed features using simple random linear projection matrices, and then these latent concepts determine performance based on a cosine similarity between the concept latent space and the item’s concept space score, where the latent spaces are weighted based on user performance. If a user is good at a concept, and there is high overlap between that concept and the item’s latent score, then the user has a high performance. We generate 5000 samples from this dataset for 5 users each (25000 items) for training. We also compare training performance on one user versus on all users, referring to them as “Multi user simulated data” and “Single user simulated data”.

2.2 Targeted similarity network

2.2.1 Network Architecture

Here we develop a deep learning framework for learning concept embeddings that integrates behavioral and item-features (see figure 3). We construct a targeted similarity network that learns an embedded representation for similarity comparison, based on item performance. We attempt to learn a similarity space for item features v_i by learning a predictive model $p(r_i|v_i, v_j, r_j) = \sigma(c_{ij} \times r_j)$, that is we want to predict the performance of problem i from problem j and the similarity between the two (where σ is a sigmoid function).

Categorical features are embedded into a linear space, using a learned embedding matrix E_1 . We then employ a deep set architecture to deal with permutation invariance in the subproblems. Consider an item that involves a series of subproblems to be solved, each of which can be solved in any

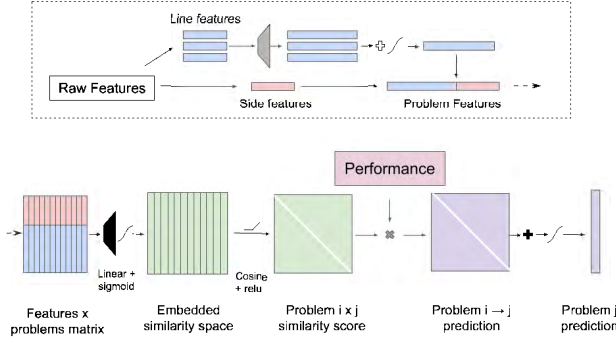

Figure 3: Top: Network feature embedding component, where embedded features are then passed into the main network. Features are processed through these steps, separating line features to deal with permutation invariance, and then concatenated with side features. Bottom: Main network embedding, where features are embedded into a similarity space and similarity scores between all items are computed for prediction.

order. We can then consider the problem P to be composed of subproblems p_k , and side features s . Therefore: $P_i = \{p_1, p_2, \dots, p_m, s\}$, where the indices k of the subproblems may be swapped, and m is variable across problems (i.e., the number of sub-problems can vary, such that P_i might include only a single subproblem). Each subproblem has an associated feature vector of length l . As mentioned above, each subproblem has one categorical feature labeled a_k , we embed with the same matrix (note $p_k = [a_k, z_k]$ with non-categorical z_k features). To model the permutation invariance, we use sum-decomposition via latent space as in [10], to produce a single vector per problem that represents the combined influence of all subproblems.

Each problem also has a vector of side features, which includes a feature coding the number of subproblems. The decomposed subproblems are then concatenated with the side features to produce an overall item feature set, which we label x_i for problem i . We can describe this initial feature embedding process with the set of functions (see figure 3):

$$\hat{a}_k = E_1^T a_k \text{ for each } a_k \text{ in } P_i \quad (1)$$

$$v_i = \sigma(\text{sum}_m(E_2^T \hat{P}_i)) \quad (2)$$

$$x_i = [v_i, s_i] \quad (3)$$

where \hat{a}_k are the embedded categorical features for each subproblem and E_2 is the linear weights for the sum-decomposition (size l by e_2 latent space). The sum is down the same dimension as the stacked feature vectors, such that v_i is length e_2 . Then we compute item similarity by projecting the embedded feature matrix X to the similarity space S , and take the cosine similarity of S with itself: Item performance is then predicted off of the similarity score and other item's performance (represented -1 or 1 for incorrect, correct), and passed through a sigmoid function. Items with high similarity are then predicted to have similar performance, while those with low similarity are not. Since our interest is in

Table 1: Final AUC Test Scores

Model	Dataset	AUC Score
Network	Single-user sim	~ 0.999
Network	Multi-user sim	0.998
Network	Mathemarmite	0.518
Subject average	Mathemarmite	0.762
Item average	Mathemarmite	0.541

the similarity space itself, we allow all items in a batch to predict the performance of all other items, by adding their prediction.

$$S = \sigma(W^T X) \quad (4)$$

$$C = \text{sim}(S) \quad (5)$$

$$\hat{R} = CR \quad (6)$$

Where R is a batch-size square matrix of the response vector copied down the rows. $\text{sim}(S)$ computes the similarity score of all items using positive cosine similarity, $\text{sim}(s) = \text{relu}(\hat{S}\hat{S}^T)$ where $\hat{S} = \frac{S}{\|S\|}$. This allows C to take on the interpretation of item by item similarity matrix where C_{ji} (jth row and ith column) being the $i \rightarrow j$ similarity for prediction. The final prediction is then made by summing across \hat{R} column space (ignoring the diagonal $i \rightarrow i$ similarity), that is $\sum_i \hat{R}_{ji}$ to produce a vector of predicted j responses when passed through a final sigmoid output.

3. RESULTS

All network experiments are coded using Pytorch. Networks are trained using Binary Cross Entropy loss. Hyperparameter selection is done via cross-validated AUC scores on 100 runs, finding an embedded similarity space of 7 for Mathemarmite and 5 for both simulated datasets. We then train these networks on 500 runs (epochs) with those parameters using a 20% train-validation split (split trials selected at random), showing both train and validation AUC scores in figure 4.

We also compared against two baseline models: predicting performance off of each subject's average performance, and predicting performance off of each items's average performance (leaving out the given trial in both cases). Final AUC test scores are shown in table 1.

Note that AUC of 0.5 is by chance with 1 being perfect, so the Mathemarmite dataset is just above chance performance.

3.1 Visualization

The significant value of this network is in being able to construct a similarity space to compare the items, and then interpret the resulting space. To visualize the space, we use t-SNE [5], which allows us to project the similarity weights of items down to a 2D space for visualizing clusters. As shown in figure 5, we are able to reconstruct our latent concept space in the simulated dataset using the network (single-user). Similar projection exists for multi-user dataset.

Figure 4: AUC scores across training epochs. Black line indicates chance performance, while dashed line is baseline prediction in the Mathemarmite dataset (average subject performance).

Figure 5: Recovered latent spaces in simulated data (single user). Colors correspond to arbitrary latent concept.

While we do not have ground truth for the Mathemarmite dataset, we can still perform the same visualization. However, given our final performance score, we cannot directly interpret the resulting space, and it is therefore not a meaningful latent concept space.

4. CONCLUSION

In this paper we developed a novel network for learning a similarity space for educational test data, and applied it to simulated and real data. Given that the performance on the simulated dataset is high, the network is able to reconstruct the latent space of items appropriately, given the assumptions of the underlying data generative process. However, the network does not perform well on the collected dataset. Given that we can predict line performance using a standard logistic regression model (AUC at ~ 0.65 , where line features predict line performance), item features are informative of line performance, and therefore item performance (recall that items are made of multiple lines). A possible issue with the Mathemarmite dataset is that we intermix different users, with high variability across users. Given the adaptive algorithm that underlies Mathemarmite, only players with higher performances will attempt otherwise harder problems, making it more difficult to separate user and item relations.

An important limitation of our current model is it does not incorporate individual user differences in terms of the found similarity space, therefore it cannot account for changes in a user performance as well (i.e., due to learning); our network cannot learn what it cannot represent. An alternative is to incorporate user-level features, and structure the network in a bilinear fashion, much like standard item response theory. In other words, expert users likely have a different concept space than novice users. Future work involves developing a network that instead allows multiple similarity spaces across users. Such additional complexity should capture the underlying structure of the Mathemarmite dataset and lead to insights on number representational space.

ABSTRACT

In this paper, we propose and evaluate a decision support system (DSS) to predict the topic of discussion forum posts among categories: *Social*, *Concept*, *Assignment*, and *Others*, in Massive Open Online Courses (MOOCs). The DSS uses two supervised machine learning (ML) models- Logistic Regression and Multinomial Naïve Bayes to output: two most-likely categories with associated prediction probabilities, and a surety indicator (High, Medium, or Low) of prediction. We evaluated the DSS on manually-labelled discussion posts from two programming related MOOCs offered on different platforms and the ML models being trained on the same and different course. Our results indicate that: a) the prediction performance of DSS is better when trained on labelled data from the same course, b) when trained on data from another course, the DSS performs better if training data is sampled to reduce the bias in distribution of categories, and c) providing the two most-likely categories is helpful for indicating the smaller categories that are usually difficult to predict by ML models. This DSS can help instructional teams to better manage the MOOC discussion forum and learners to easily navigate and find relevant posts.

Keywords

MOOC Discussion Forum, Text Classification, Machine Learning, Decision Support System, Logistic Regression, Naïve Bayes

1. INTRODUCTION

Discussion forums are the primary medium of social interaction in MOOCs and have been found to help improve learners' understanding of course material as well as provide a community learning experience in an online environment [1]. Involvement of instructor and teaching assistants can encourage learner participation and improve quality of discussion [2]. However, managing the discussion forum of a large MOOC can be challenging for the instructional team due to large number of participants and multiple ongoing threads. Similarly, for learners, it can be difficult to navigate through and find relevant posts. A DSS that can organize the discussion forum posts topic-wise and highlight posts that require attention can be very helpful.

Some MOOC platforms, such as EdX, ask users to input the topic of discussion by selecting from a predefined list of topics when

creating a discussion post [4], but this approach relies on users to correctly input the topic and having an exhaustive list of predefined topics ready. Earlier studies have examined various approaches for addressing the issue of unorganized MOOC discussion forums [3], such as: (a) classifying content related discussion forum posts using machine learning for models trained on same course and different course [5]–[8] (b) identifying user posts that need instructor attention using supervised machine learning models [1] [9], (c) analyzing discussion posts using topic modelling [10], and (d) identifying question related threads and their potential answers in discussion forum [11].

Previous studies have used different levels of categorization of MOOC discussion posts, such as, “content-related” and “non-content related” [7], relatively broader categories such as “Course material”, “Course Logistics”, and “General (all other types)” [10], or more specific set of categories such as “Content”, “Other Coursework”, “Social/affective”, “Technology”, “Policies” and “Other” [12]. There are various advantages and challenges associated with very broad or very specific categories of discussion posts in terms of informativeness and prediction capability of machine learning (ML) models. While very broad categories can be easily predicted by ML models, there can be multiple sub-categories within each of the broad category. On the other hand, very specific categories are more informative, but predicting them accurately using ML can be challenging due to issues such as imbalanced data distribution among categories and very few training cases of smaller categories. Depending on the purpose of classification and availability of training data, an optimum set of categories should be determined.

2. PROPOSED SYSTEM

The DSS combines the prediction outputs of two classical ML models- Multinomial Naive Bayes (MNB) [13] and Logistic Regression (LR) [14] to predict the category of discussion based on the first post of a discussion thread, as shown in Figure 1.

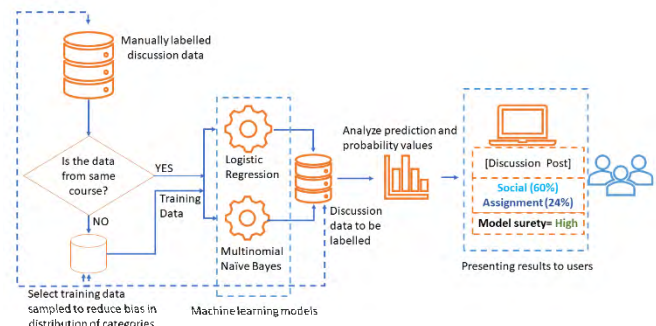

Figure 1: Schematic diagram of proposed DSS

We selected these two ML models as they both have been widely used for text classification, are scalable, and output the probability

Gaurav Nanda and Kerrie Douglas "Machine Learning Based Decision Support System for Categorizing MOOC Discussion Forum Posts" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 619 - 622

of prediction along with the predicted category- which is an important component of the proposed DSS, that has been similarly used in healthcare and other domains [15], [16], [17]. The prediction probability is informative to the end-user as it indicates the confidence in predictions. The DSS prediction probability- $Prob_DSS(Category)$ for each category is derived by averaging its prediction probabilities outputted by the LR and MNB models. The DSS outputs two most-likely categories along with their corresponding $Prob_DSS(Category)$ based on largest and second largest $Prob_DSS(Category)$ values.

The DSS also outputs a model surety indicator- DSS_Model_Surety that can assume values *High*, *Medium*, and *Low* based on following conditions: a) if predictions of LR and MNB do not agree, then *Low*, b) if MNB and LR predictions agree and $Prob_DSS_Max$ (i.e., maximum $Prob_DSS(Category)$ among all categories) < 0.5 , then *Medium*, and c) if MNB and LR predictions agree and $Prob_DSS_Max \geq 0.5$, then *High*. The threshold for $Prob_DSS_Max$ was set to 0.5 as it meant that both LR and MNB predicted that category with relatively high confidence. This threshold can be changed depending on the number of categories and objective of DSS. As shown in Figure 1, the DSS uses a strategy for providing training data to the ML models depending on availability of manually-labelled data from same course. This process is also discussed later in the paper.

3. METHODS

We used manually annotated discussion forum posts from two computer programming related MOOCs offered on different platforms, both with approximately 4800 enrollees, referred to as FL and EdX in the rest of the paper. FL, titled “R for Data Science”, was offered on the FutureLearn platform in Spring 2017 and had about 900 discussion threads with multiple posts in each thread. EdX, titled “JAVA Programming”, was offered on EdX in Summer 2017 and had about 300 discussion threads.

For assigning categories to each thread, three researchers independently coded a sample of 100 threads and then compared and refined the emergent themes. Using the refined themes, they independently assigned codes to a different sample of 50 comment threads and reconvened to finalize the themes that describe the main content of threads. These themes were: *Social* (introductions, reasons to take the course, expectations, experience etc.), *Concept* (questions and comments about course content covered in lecture videos or readings), *Assignment* (discussion related to assessments), and *Other* (course policy, website issues, other technical issues, general feedback, and anything that did not fit in remaining categories). Using this coding scheme, all discussion threads for both courses were analyzed such that each thread was assigned a code by two researchers. Any disagreement was reviewed by all three researchers and a consensus was achieved.

We used Sensitivity and Positive Predictive Value (PPV) as the prediction performance measures for individual categories:

$$Sensitivity = \text{True Positives} / (\text{True Positives} + \text{False Negatives})$$

$$PPV = \text{True Positives} / (\text{True Positives} + \text{False Positives})$$

For evaluating the overall performance, we used the measures WAvG-Sen (the overall Sensitivity, which is weighted by the size of the category), UAvG-Sen (simple average of Sensitivity across all categories, that does not account for category size), and UAvG-PPV (simple average of PPV across all categories). For classification purposes, we used only the first posts of the discussion thread, as done by [5], because the primary topic of discussion is usually set by the first post of the thread, although it

can sometimes change later on. This approach can also help the instructional team in prioritizing their responses to questions. We implemented the MNB and LR models using the machine learning package WEKA [18] and its LIBLINEAR library [19] for L2-Regularized Logistic Regression model. We preprocessed the text by deleting non-alphanumeric characters and removing stopwords using the Rainbow [20] stopword list in WEKA. We conducted following set of experiments for performance evaluation:

Experiment 1: We first evaluated the baseline performance of the ML models when trained on data from same course. We used the 10-fold cross validation method to calculate the Sensitivity and PPV of LR and MNB models for both courses- FL and EdX.

Experiment 2: We then examined the performance of ML models trained on data from a different course on a different platform in a similar area. We used the entire data from one course as the training set and the entire data from another course as the prediction set resulting in following combinations of training and prediction (test) sets: Train: EdX, Test: FL and Train: FL and Test: EdX.

Experiment 3: FL and EdX had significantly different distribution of categories, which can lower the prediction performance of ML models when trained on data from another course. We examined the performance of ML models with modified training sets having similar distribution of categories as prediction set by under-sampling cases from high-frequency categories. We did not aim to match the exact distribution of the prediction set; our idea was to reduce the bias in the distribution of categories at a broader level. The composition of original (FL and EdX) and modified training sets (FL-Mod and EdX-Mod) is shown in Figure 2. The resulting combinations were: Train: EdX-Mod, Test: FL and Train: FL-Mod and Test: EdX.

Figure 2: Distribution of categories in training datasets

Experiment 4: Both courses were divided into random non-overlapping training (80% data- EdX-train and FL-train) and prediction sets (remaining 20% data – EdX-test and FL-test). The performance of ML models and DSS were examined on:

- training data from same course, i.e., following combinations- Train: EdX-train, Test: EdX-test, Train: FL-train, Test: FL-test.
- training data from another course sampled to have similar distribution of categories, i.e. following combinations- Train: EdX-Mod, Test: FL-test, Train: FL-Mod, Test: EdX-test.

4. RESULTS and DISCUSSION

Experiment 1: The 10-fold cross validation results of LR and MNB models on FL and EdX are presented in Figure 3.

Figure 3: Prediction Results of 10-fold Cross Validation

As shown in Figure 3, both ML models had similar overall prediction performance (columns WAvG and UAvG) for EdX and

FL. Among different categories, performance for the larger categories, i.e., *Social* and *Assignment* for EdX, and *Social* for FL was relatively better than smaller categories. We can see a larger gap between the WAvg (Sen and PPV) and corresponding UAvg for FL, which is probably due to the heavily imbalanced distribution of categories in FL, with 63% cases belonging to a single category- *Social*. It is also to be noted that the prediction performance of *Other* is lowest in both the courses. It may be due to the catch-all nature of definition of the category *Other* i.e. posts that are not classifiable in any other category, which can lead to a mix of different kinds of posts in this category and increases the chances of misclassification.

Experiments 2 and 3 results are presented in Figure 4.

Figure 4: Prediction performance of ML models when trained on data from another course with different sampling methods

As shown in Figure 4, the prediction performance of ML models was considerably better when they were trained on the modified training sets as compared to entire data from another course, most noticeably in case of Test: EdX-test, with Train: FL and Train: FL-mod, possibly because FL data distribution was more skewed.

Experiment 4: First, the performance of ML models for training sets from same and another course are presented in Figure 5.

Figure 5: Prediction performance of ML models when trained on same and different course

As shown in Figure 5, both ML models yielded similar overall prediction performance with training data from same course (WAvg-Sen range 0.76-0.79), which was considerably better than training data from another course -- about 10% better WAvg-Sen for Train: EdX-Mod and Test: FL-test, and about 20% better WAvg-Sen in case of Train: FL-Mod and Test: EdX-test. It is to be noted that neither LR nor MNB model always performed better than the other. Therefore, it is advantageous to use predictions made by both ML models in the DSS for robustness-- which was also evident in our results. The prediction performance of DSS' top-prediction is presented in Figure 6. From Figures 5 and 6, we can observe that the DSS performed better than the individual ML models (on both WAvg and UAvg) when trained on data from

another course. For training on data from same course, the DSS performed close to the better-performing ML model.

Figure 6: Prediction performance of DSS' top-prediction

The smaller categories- *Other* and *Concept* were most difficult to predict for ML models as well as DSS (top-prediction) even with training data from same course. In order to address this issue, we designed the DSS to provide top-two predictions to users with associated probabilities. The intuition behind this approach was: for the cases corresponding to smaller categories, the second most-likely category would indicate the correct category.

Top-2 Predictions: The above intuition was validated by analyzing the top-two predictions of the DSS as shown in Figure 7.

Figure 7: Results for DSS Top-1 and Top-2 predictions

We observed considerable improvement in Sensitivity of the smaller categories (*Other*, *Concept*, and *Assignment*) between Top-1 and Top-2 predictions. Sensitivity for Top-2 predictions were calculated by counting cases in prediction set as 'True-Positive' if the manually assigned category was among DSS' top-2 predictions.

Model Surety: As mentioned before, the Model Surety is determined based on ML model agreement and *DSS_Prob_Max* value. In Table 1, for conditions where the ML models were trained on data from different courses, we present the distribution (Minimum, Maximum, and Average) of *DSS_Prob_Max* values for different scenarios where the LR and MNB models agree or disagree, and if the predictions were correct or not. In Table 1, column N indicates number of cases in test set for each criterion.

Table 1: Range of *DSS_Prob_Max* for different scenarios

Case ID	Predictions Correct?	LR = MNB?	Train: FL-Mod Test: EdX-test				Train: EdX-Mod Test: FL-test			
			DSS_Prob_Max				DSS_Prob_Max			
			N	Min.	Max	Avg.	N	Min.	Max	Avg.
C1	Y	Y	23	0.37	0.94	0.75	98	0.47	0.97	0.75
C2	N	Y	13	0.35	0.58	0.5	32	0.41	0.95	0.63
C3	Y	N	10	0.3	0.61	0.46	13	0.34	0.58	0.42
C4	N	N	12	0.27	0.48	0.39	18	0.32	0.61	0.4

As shown in Table 1, when the model predictions agreed (case ids C1 and C2) the chances of the prediction being correct were higher 64% (23/36 cases) for EdX-test, and 75% (98/130 cases) for FL-test, as compared to when model predictions did not agree- 45% (10/22 cases) for EdX-test and 42% (13/31 cases) for FL-test. It is also to be noted that the average *DSS_Prob_Max* values were considerably higher when the ML models agreed and the predictions were correct, as compared to other scenarios. This means that when the DSS would indicate *High* Model Surety, it is likely to give highly accurate predictions. This is also demonstrated

in the results presented in Table 2, where we show the overall DSS prediction performance (Top-1 and Top-2 predictions) for different Model Surety values when the ML models were trained on data from another course. In Table 2, column N represents number of cases for each criterion, TP indicates True Positives, and %Correct indicates proportion of correctly predicted cases, i.e., TP/N.

Table 2: DSS prediction performance at diff Model Surety

Data		Model Surety	N	Top-1		Top-2	
Train	Test			TP	%Correct	TP	%Correct
EdX-Mod	FL-test	High	122	96	0.79	106	0.87
		Med	8	2	0.25	2	0.25
		Low	31	13	0.42	17	0.55
FL-Mod	EdX-test	High	28	21	0.75	24	0.86
		Med	8	2	0.25	5	0.63
		Low	22	10	0.45	15	0.68

As shown in Table 2, when the Model Surety was *High*, %Correct was substantially higher than when the Model Surety was *Med* or *Low*. It is also to be noted that there were fewer cases (N) with *Med* surety as compared to *Low* surety because when the ML models disagreed, then *DSS_Prob_Max* was likely to be less than 0.5.

5. CONCLUSIONS

In this study, we proposed a machine learning based DSS to predict the broad category of MOOC discussion forum thread based on its first post and provide explanatory output to users. Based on the preliminary evaluation of the DSS, we can conclude that the DSS would perform better when manually annotated data from previous runs of the same MOOC is available. Annotated data from a similar course can also result in reasonable performance if training data sampling is done to remove the bias in data distribution, and, if possible, match the distribution in prediction set. The results also indicated that by providing the top-2 predictions, the DSS can tackle the issue of poor prediction accuracy of smaller categories by ML models. Because of the simple underlying ML models, the DSS is very scalable and can be easily integrated into any existing MOOC platform with suitably customized user interface. The proposed DSS would be helpful in organizing discussion forums better and thus improving learner participation. Future work can examine topic models for estimating the distribution of categories in unlabeled data, including other ML models in the DSS, and conducting user studies on its utility and usability in MOOCs.

ABSTRACT

In this paper we propose a hybrid architecture combining Deep Neural Network architectures with expert's knowledge to automatically evaluate socio-moral reasoning maturity. Socio-moral reasoning represents a key ability to sustain efficient adaptive social interactions. In the proposed solutions, expert knowledge is first computed using NLP and information retrieval techniques and then added to the DNN architecture using the attentional mechanism. It uses pre-annotated textual data and a coding scheme (SoMoral) applied by experts in psychology. State-of-the-art text classification algorithms (Support Vector Machine, Naive Bayes, etc.) achieved very low results in our context in contrast to LSTM and CNN (when combined with expert knowledge). Our solutions were compared to four models: a CNN-only model, an LSTM-only model, a CNN and an LSTM models where the expert knowledge is concatenated directly with the data (instead of using attention). Experiments show that our models can accurately predict the level of socio-moral reasoning skills. Our findings suggest the need for hybrid neural networks that integrate prior expert knowledge (especially when it is necessary to compensate the strong dependency - of deep learning methods - on data size or the possible unbalanced datasets).

Keywords

Convolutional Neural Networks, Long Short Term Memory, Socio-Moral Reasoning skill, Serious Game, Learner Model, Expert Knowledge, Hybrid Neural Networks.

1. INTRODUCTION

Socio-Moral Reasoning (SMR) is a socio-cognitive construct essential for decision-making, as well as social interaction adaptation. It is commonly defined as "how individuals think about moral emotions and conventions that govern social interactions in their everyday lives" [1]. Being able to predict and diagnose one's socio-moral reasoning skill level (or ability) is a key step for quantifying peoples' so-

cial functioning and can be used to identify those at risk for maladaptive social behaviour. This diagnosis could help orient people towards appropriate services or provide adequate support to improve this skill's development. The Socio-Moral Reasoning Aptitude Level (So-Moral)[4] task is a computer-measured walkthrough in which children and adolescents are presented with visual social dilemmas from everyday life. They are then asked to verbalize how they would react in this situation, justifying their answer. The participants' answers are recorded verbatim in transcripts that are subsequently scored manually by experts using a moral-maturity coding scheme inspired by the Kohlberg's theory of moral development [7]. Verbatims are short or long text containing at least one sentence. Each socio-moral reasoning rating was well documented by experts using annotated data. The goal was to put together these two kinds of data to build an accurate model for the automatic prediction of reasoning skill level. Using annotated data only would not give us good results in this context. Therefore we propose a hybrid model that combines expert knowledge with DNN (Deep Neural Networks) architectures (especially CNN and LSTM) using the attentional mechanism [11] for predicting the level of SMR skill of an individual based on his justifications when solving socio-moral dilemmas. The developed solution extends the learner/player model in a serious game called LesDilemmes [13].

2. RELATED WORK

Deep learning architectures are data-driven techniques, therefore their performance is strongly dependent on the amount and the quality of the data. However, many contexts have only a limited amount of data while providing prior expert knowledge. Towel et al. [14] defined hybrid learning techniques as "methods that use theoretical knowledge of a domain and a set of classified examples to develop a method for accurately classifying examples not seen during training". By doing so, a hybrid learning system should learn more effectively than systems that make use of only one of the information sources. There exist very little research focusing on the combination of the a priori expert knowledge and deep learning architectures. Among them, Towel et al. [14] (which might be the first paper to discuss this matter) proposed a hybrid system called KBANN (Knowledge-Based Artificial Neural Networks). It maps expert knowledge, represented in propositional logic, into neural networks and then refines this reformulated knowledge using back-propagation. Coro et al. [3] combined Neural networks (NN) with simulated expert knowledge. Zappone et al. [16]

Ange Adrienne Nyamen Tato, Roger Nkambou and Aude Dufresne "Hybrid Deep Neural Networks to Predict Socio-Moral Reasoning skills" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 623 - 626

recently did the same by combining expert knowledge and Artificial Neural Networks (ANN) in order to optimize wireless communication networks.

In the educational domain, a priori expert knowledge is usually available and generally used to build Intelligent Tutoring Systems (ITS). In other domains, expert knowledge can be available through books or previously built models (such as rules-based models). We believe that this a priori expert knowledge, sometimes acquired over decades of intense research, cannot be dismissed and ignored. In the present paper, in particular, we put forth an approach that uses attentional mechanism and capitalizes on the availability of (possibly simplified or inaccurate) theoretical models in order to reduce the amount of empirical data to use and the complexity of deep artificial training neural networks. To our knowledge no research has proposed to combine a priori knowledge with deep learning architecture using the attentional mechanism as of yet. Moreover, no research in the educational data-mining domain has yet focused on this matter despite the availability of expert knowledge. We applied the proposed solution to the automatic detection of socio-moral reasoning skill level of learners (players) in a serious game.

3. CONTEXT

One of the objectives underlying the development of the proposed model is to implement the automated scoring mechanism in a serious video game called LesDilemmes [13]. It is a first-person serious game which aims to assess and train the social reasoning skills of the player. Through this work, we aim to build an effective model of the socio-moral facet of the learner/player. The level of socio-moral reasoning skill of an individual is determined from its verbal justifications provided when solving the dilemmas. This involves the implementation of a model for automatic measurement of this level during the game. We have a dataset of verbatims coming from the SoMoral experimentation already annotated by experts and a description (a paragraph with key concepts) associated with each different level (or class) of maturity (skill). This paper describes a machine learning model that can accurately assess the socio-moral reasoning skill level of a player based on his verbatim.

The original So-Moral task includes five different levels of socio-moral reasoning skill[1] : (1) Authoritarian-based consequences, (2) Egocentric exchanges, (3) Interpersonal Focus, (4) Societal Regulation and (5) Societal Evaluation. Transition levels (i.e. 1.5, 2.5, 3.5, 4.5) are used to account for verbatims that provide elements of two reasoning stages and show a sequential progression from one stage to another. Occasionally, a verbatim is assigned to two different closed levels (1 being the maximum deviation) when two independent experts annotate the data for rater reliability purposes. A first convolutional neural network has been proposed to automatically detect the socio-moral reasoning skill. Despite the high accuracy reported (92 %) [13], the model was not able to predict when a person has a socio-moral reasoning level of 2, 3 or 5. All the predictions were either levels 1 or 3 due to the unbalanced dataset. This paper addresses this issue in order to ensure the accuracy of the learner model for a better support of the learning process in the serious game.

4. THE PROPOSED HYBRID ARCHITECTURES

4.1 Expert Knowledge

Expert knowledge represents the proficiency shown by experts in a particular domain. In the educational domain, expert knowledge is generally available. For example, in [12], expert knowledge was used through a Bayesian network to predict logical reasoning of students. There are many ways to make the expert knowledge usable by a computer. A well-known approach consists in building a rule-based system [5, 2]. In our context, where we only have access to description (in textual form) of each of the levels, we employed two different techniques related to IR (Information Retrieval) and NLP (Natural Language Processing): the Word Movers' Distance (WMD) [8] to compare the meaning of texts, n-grams, and stemming to test whether verbatim contain those specific elements extracted for each level. For each verbatim the WMD calculation provided us with a vector of length 5 where each entry is the similarity between the verbatim and the description of the corresponding socio-moral reasoning skill level. The values range between 0 and 1. For each verbatim, the n-grams provided us with a vector of size 5 where each entry represents the number of n-grams and synonyms of each level found in the verbatim. We finally applied the softmax function to the resulting vector which was added to the one generated by the WMD method.

4.2 Hybrid Architectures

Neural networks (NN) are able to learn any function that maps inputs to outputs. They are particularly salient when there is a lot of data available. Neural networks often perform well when compared to other machine learning algorithms. According to LeCun and his team [9], deep learning allows computational models composed of multiple layers of processing (e.g. neural networks) to learn data representations at multiple levels of abstraction. There exist several deep-learning architectures. However, we will focus here on LSTM and CNN, as they were proven well suited for text classification [17].

Neural Networks are layered graphs with the output of one node feeding into one or many other nodes in the next layer. Their inner architecture makes it difficult to incorporate domain knowledge to the learning process [10]. Our solution is to constrain the model to pay attention to what the expert knowledge says about the current input x . It aims to incorporate the expert's final prediction about the input rather than how the expert knowledge is processed. Since attention [15] is a memory-access mechanism, it fits well in this context where we want the model to have access to the expert knowledge during learning, as its memory. In other words, the DNN will "consult" the expert before taking the final decision. Attention mechanism equips a neural network with the ability to focus on a subset of information. The importance the DNN model will accord to what the expert said is computed (learned) through attentional weights (W_c and W_a). W_c represents the weights measuring the importance of the expert knowledge and the learned features to the final prediction vector. W_a corresponds to the weights calculating the importance of each feature learned by the DNN on each feature of the expert knowledge. Thus, the model will focus on what the expert knowledge says before taking any

decision. By integrating the expert knowledge in the DNN using the attention, the model iteratively processes the a priori knowledge by selecting relevant content at every step. To present our approach, we will consider the LSTM model. However, this can also be applied to the CNN as well. In the original attentional mechanism, the attentional vector is computed from the target hidden state h_t and the input hidden state (which is replaced by the vector representing the expert knowledge). Given the hidden state h_t of the LSTM, and the expert-side context vector c_t^e , we employ a concatenation layer to combine the information from both vectors to produce the attentional hidden state a_t as follows:

$$a_t = \tanh(W_c[c_t^e; h_t]) \quad (1)$$

Please note that h_t could be the hidden state of the last cell of the LSTM or the hidden states of all the cells. For the CNN, h_t represents the output that has been flattened. The attentional vector a_t is then fed through the dense layer of the model to produce the predicted socio-moral reasoning skill level. Now, the expert-side context vector is computed as follows :

$$\begin{aligned} \text{score}(e_s, h_t) &= h'_t \cdot e_s \cdot W_a + b \\ \alpha_{t,s} &= \frac{e^{\text{score}(e_s, h_t)}}{\sum_{j=1}^s e^{\text{score}(e_j, h_t)}} \\ c^e &= \sum_s \alpha_{t,s} \cdot e_s \end{aligned} \quad (2)$$

Where e_s ($s=5$) is the current socio-moral reasoning skill level (normalized) computed from the expert knowledge and $h'_t = \text{softmax}(h_t)$. e_s is a vector of length equals to the number of levels (5 in our case) and each entry represents the predicted probability by the expert that the verbatim belongs to each of the classes. We applied the *softmax* function to h_t to have a fair comparison with e_s . *Score* is a content-based vector [11] which computes the correlation (alignment score) between the expert knowledge and the features learned by the network : how well the expert knowledge and the features learned from data are aligned. The model assigns a score $\alpha_{t,s}$ (vector of size 5 in this case) to the pair of feature at position t and expert knowledge (e_s, h_t), based on how well they match. The set of $\alpha_{t,s}$ are weights defining how much of each expert knowledge features should be considered for each output (final prediction). Our code for this attentional-based a priori expert knowledge is publicly available on github ¹.

5. EXPERIMENTS

In order to empirically evaluate the proposed solution, we investigated six different models: a CNN (cnn-only), an LSTM (lstm-only), a CNN where expert knowledge was concatenated to the features learned (cnn-expert), an LSTM where expert knowledge was concatenated to the features learned (lstm-expert) and finally the proposed models cnn-expert-att (a CNN where expert knowledge was concatenated to the features learned + knowledge-based attention) and lstm-expert-att (a LSTM where expert knowledge was concatenated to the features learned + knowledge-based attention). We used the same parameter initialization for all the models. Adam [6] was used as the optimizer with a learning rate

¹<https://github.com/angetato/Combining-DNN-With-Expert-Knowledge-ToPredict-Socio-Moral-Reasoning-Skills>

Figure 1: Final model for predicting socio-moral reasoning skill level. Each sub model is specialized for the prediction of levels specified between parenthesis. Each model is either LSTM or CNN combined with expert knowledge and the attentional vector.

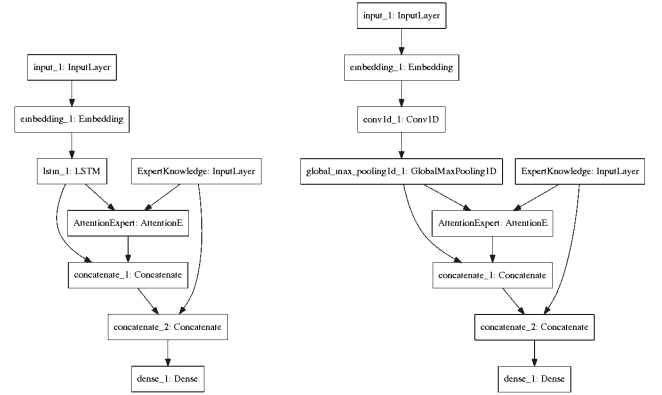

Figure 2: The proposed hybrid architecture using LSTM (left) or CNN (right) for the prediction of socio-moral reasoning level.

set to 0.001. The algorithms were implemented using Keras² and the experiments were done using the built-in Keras models, making only small edits to the default settings. The dataset consists of a benchmark of 731 verbatims (written in French) manually annotated by experts. Verbatims are not equally distributed between classes (unbalancing data).

5.0.1 Proposed Models:

The models take as input the verbatims that have been pre-processed (tokenization, text to sequence, etc.) and vectored. The vectors are then passed to the embedding layer. In figure 2 (left), the embedding vectors are passed to the LSTM layer (note that we have only considered the output of the last cell). The expert knowledge and the output of the LSTM are then passed to the expert knowledge-based attention. The attentional vector is merged with the expert knowledge and the output of the LSTM. The concatenation is passed to the last layer for the prediction. This process is the same for the CNN (see figure 2(right)), except that the knowledge-based attention layer takes as input the expert knowledge and the result of the pooling operation applied to the output of the CNN. To evaluate the added value of this knowledge-based attention, we have considered two similar models (cnn-expert, lstm-expert) to those shown in figures. However, those models do not have the knowledge-based attention layer. They are used as a comparison with the proposed solutions.

5.1 Results

²<https://keras.io/>

All the models have been trained on 80% (with 20% as validation data) of the data and tested on the remaining 20 %. The results are shown in table 1. As we can see, models that take into account expert knowledge perform well for the prediction of classes with few samples compared to others with no expert knowledge (f1score for classes 2, 4, and 5). This is due to the fact that experts do not need data to make decisions because their decisions are based on their own knowledge. This suggests that, incorporating expert knowledge to neural models improves the classification even when the dataset is unbalanced. Also, even if there is not a huge amount of training data, the models are still capable of better generalize on unseen data.

Table 1: Overall precision, recall, f1score and accuracy of all the models.

Models	Precision	Recall	f1-score	Acc
Expert-Only	0.47	0.40	0.38	0.40
cnn-only	0.58	0.53	0.49	0.53
lstm-only	0.42	0.43	0.42	0.43
cnn-expert	0.62	0.62	0.62	0.62
lstm-expert	0.54	0.53	0.51	0.53
cnn-expert-att	0.67	0.65	0.63	0.65
lstm-expert-att	0.59	0.60	0.58	0.60
Final Model	0.72	0.75	0.73	0.75

6. CONCLUSION

We have proposed a model able to predict with over 75% accuracy the socio-moral reasoning skill level based on textual verbatim and a priori expert knowledge. In particular, we proposed a simple but efficient way to integrate expert knowledge into deep neural networks architecture using the attentional mechanism. Our proposed model is also intended to help experts on the annotation of verbatims. Results were very promising. Contrary to the state-of-the-art techniques in text classification, the solution we proposed achieves best results in our context. This is mainly due to the deep structures that can learn useful features from data and also the a priori knowledge that can leverage unbalanced data. Based on theoretical arguments and numerical evidence illustrated in the present work, it is possible to conclude that the a priori expert knowledge provides unique insights to complement and improve DNN data-driven approaches. It is our hope that this paper will spur the interest of our research community, towards developing efficient ways of combining neural networks architecture with theoretical prior knowledge. The work presented in this paper has introduced a simple approach towards this direction, which, however, only represents the tip of the iceberg.

ABSTRACT

The National Exam of Students Performance (ENADE), organised by the National Institute of Educational Studies and Research Anísio Teixeira (INEP), aims to evaluate the performance of undergraduate students in relation to the syllabus, as also skills and competencies acquired during their academic training. The result of this evaluation is considered to be a part of a grade for undergraduate programmes and is also used to assess the general quality of Brazilian higher education. The main goal of the present research is to understand the relationship between the curricular components associated with the questions of the ENADE exam. We investigate the existing bias in the students' answers that may reveal a tendency towards specific fields, possibly resulting in better scores for certain programmes. Open data for the last two years of ENADE for the Information Systems (IS) undergraduate programmes were collected and pre-processed by using data techniques for cleaning, transforming and normalisation. In order to measure the bias in the probability distributions of question answers, the information theory framework was applied. Our experiments revealed structures among questions by conditional entropy. Such structures may suggest underlying relationships between questions, not only for those of the same subject but also for questions on dependent subjects. Our findings show that some questions may give an advantage over at most 15.2% on other questions.

Keywords

entropy, analytics, bias selection, higher education

1. INTRODUCTION

Instituted by Brazilian Federal Law, the National Exam of Students Performance (ENADE) aims to evaluate and obtain a diagnosis on the quality of the undergraduate programmes in Brazil [1]. This evaluation consists of the application of a national exam for a sample of students from all Brazilian undergraduate courses, which verifies their knowl-

edge with regard to the programmatic contents foreseen in the national curriculum guidelines, and the development of fundamental skills and competencies associated with professional qualification.

Since 2004, ENADE has been organised by the National Institute of Educational Studies and Researches Anísio Teixeira (INEP), an Institution linked to the Brazilian Ministry of Education (MEC). The exam occurs once a year, but each area of knowledge is evaluated once every three years.

ENADE provides the following instruments to carry out performance evaluation: (1) a test exam for the first and final year students of each undergraduate programme; (2) an impression questionnaire, to collect students' opinions regarding the physical aspects of the test exam, such as size; and, (3) a socioeconomic questionnaire that focuses on identifying the students' social and economic profile.

The national test exam has two components: (a) questions about general training, common to all areas; and, (b) specific training questions, relative to each knowledge area. The questions regarding general training, as a whole, correspond to 25% of the final exam mark, while the specific questions have a weight of 75%. The score of the specific exam component is split into 15% of the discursive part, which is a simple arithmetic mean of all essay questions; and 85% of the multiple choice part, which is proportional to the number of correct answers, since all the multiple choice questions have the same weight.

The result of ENADE test exams is essential for advancing the Brazilian higher education system as it provides quality indicators for monitoring undergraduate programmes, being used for establishing and evaluating public policies for higher education [7]. Additionally, all ENADE data are publicly available on the INEP open data website, providing a very rich source of information about higher education in Brazil.

In this context, the present work seeks to investigate ENADE data in order to analyse information bias and the underlying knowledge structures from the students' scores. We propose a methodology to address these issues by using an information theory framework. We also investigate, with the use of information measures, possible underlying patterns among curricular components that may introduce bias into the final scores. The intuition behind this idea is to prevent favouring specific curricular components by avoiding mutual informa-

Mariana Oliveira and Carlos E. Mello "Identifying bias and underlying knowledge structures in Brazilian National Exam of Students Performance" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 627 - 630

tion shared between groups of questions. Our hypothesis lies in that the underlying knowledge structures are connected through the questions in such way that the final scores are biased towards particular curricular components, instead of those foreseen in the national curriculum guidelines.

We focused our analyses on the ENADE data of the undergraduate programmes in Information Systems (IS). The choice of IS programmes was due to our expertise and experience, which allow us to analyse the quantitative results from our prior knowledge of the area. Our analyses were carried out on the ENADE data for the 2014 and 2017 editions. These are the two most recent editions with available data¹. In these two years, Information Systems was considered as an independent area by MEC, while in the previous editions it was a part of the Computer Science area.

The research questions addressed by this work are the following: (Q.1) Is there any bias in students' answers that could lead to favouring certain undergraduate programmes over others? (Q.2) Is there any overrated curricular component due to underlying dependence structures across the exam questions? (Q.3) If the bias exists, which would be the areas with this possible advantage?

2. RELATED WORK

ENADE results along different years have been reported as an important quality indicator of undergraduate programmes in Brazil [5]. Studies have reported a certain imbalance in the curricular components behind the questions, favouring certain areas over others in the ENADE tests for the Physics [3] (reconstructs the Reference Matrix of the exam), Psychology [4] (applies a blueprint tool to evaluate the exam content validity), and Physical Education [2] (conducts qualitative approach to study the contents of the exam) undergraduate programmes.

To the best of our knowledge, there are no studies in the literature that aim to identify possible bias in the ENADE test, nor studies that use information theory to measure the amount of information between ENADE's questions.

3. DATA

We collected the microdata, composed of individual records, from ENADE exam conducted in the years 2014 and 2017. Data collection was performed through the INEP website². The microdata file is accompanied by a dictionary of variables, a user manual, the socioeconomic questionnaire and inputs for the R and SAAS programs.

The data of the 2014 edition consists of 154 variables and 481,720 undergraduate students from 33 knowledge areas. The 2017 edition contains 150 variables and 537,436 undergraduate students from 44 areas. These variables concern the course, the student, the institution of higher education, the questionnaires that come with the exam, and the students' performance.

¹ENADE's was first applied for the Information Systems undergraduate programmes in 2005; since then it has been reapplied every three years.

²<http://inep.gov.br/microdados>

From the both databases, we extracted the information of the undergraduate students of Information Systems Education who answered the multiple choice questions of the specific component. The discursive questions were not considered, there being a lot of subjectivity in the score.

The variable of interest extracted is a sequence of characters, per student, representing the score of each multiple choice question within the specific component. Each character is a code, 0 for get it wrong and 1 for score. Codes 8 or 9, showing respectively, annulment by the commission and annulment by the index of discrimination, were disregarded. We also ensured that all students answered all questions removing observations where the selected variable was zero or different in size from the total number of questions. After that, the 2014 edition was composed of 13,253 students; that of 2017, of 11,980 students.

The structure of the data was better organised to facilitate analysis. A Boolean matrix was constructed from the variable of interest, with rows representing the students and the columns corresponding to each question. The dimension of 2014 edition matrix was $13,253 \times 19$, while for 2017 was $11,980 \times 22$. Although the multiple-choice specific questions of ENADE are 27 in all, in both editions there were voided questions.

4. METHODS AND METHODOLOGY

Our approach for investigating the possible dependencies of knowledge and competence structures in the ENADE exam was based on the Information Theory framework. The motivation was the strong mathematical and statistical theory [6] that supports the empirical results. The principles of Information Theory have been widely applied to many different fields such as telecommunications, physiology, linguistics, and physics [8]. Our interest is particularly in information measures and dependencies.

4.1 Information Theory

Information Theory studies the quantification, storage and communication of information. It was originally introduced in a 1948 paper by Claude E. Shannon titled *The Mathematical Theory of Communication*, in which the author was interested in the amount of information that a communication channel would be able to transmit.

The main measure of information theory is the entropy ("H"). Entropy is a quantification measure of uncertainty [8], given by the following equation³:

$$H = - \sum_i p_i * \log(p_i), \quad (1)$$

where p_i indicates the probability of each result of a discrete random variable. Note that entropy corresponds to a function of the distribution of the random variable; referring only to its probabilities, regardless of the values it takes.

In addition to entropy, information theory also has measures that deal with a pair of random variables. The joint

³In the present work, we used log base 2. However, other bases could be used, such as 3, 4, 5, 6, 7 or 10. The base change can be made by $H_b(X) = (\log_b a) * H_a(X)$.

entropy $H(X, Y)$ quantifies the amount of information associated with the random variables X and Y taken together; the conditional entropy $H(X|Y)$ denotes the amount of information that a random variable X holds regardless of the amount of information held by Y . Finally, the mutual information $I(X; Y)$ describes the amount of information that a random variable X contains about the other variable Y [8].

We adopted the conditional entropy as being the measure of dependence between two variables, given by equation 2⁴:

$$H(X|Y) = \sum_{y \in \gamma} p(y)H(X|Y = y). \quad (2)$$

4.2 Proposed Methodology

We have proposed a methodology consisting of the steps described next and in Algorithm 1.

Algorithm 1: Pseudocode of proposed methodology

input \leftarrow Students' answers from ENADE;

$M \leftarrow$ Conditional Entropy Matrix(*input*);

$M \leftarrow$ Min Max Normalisation(M);

$G \leftarrow$ Graph From Adjacent Matrix(M);

$G.nodes \leftarrow$ Entropy($G.nodes$) ≥ 0.99 ;

$G.links \leftarrow G.links < 0.4$;

output $\leftarrow G$;

The thresholds 0.99 and 0.4 are empirical, by filtering for very high entropy questions and for an acceptable minimum value of conditional entropy between questions.

(a)Conditional entropy matrix: we developed a function for calculating the conditional entropy of each pair of random variables. This allows us to look into the relationship between questions of different areas and identify possible areas that significantly contribute to the score of others. As input, this function receives the Boolean matrix from the pre-processing phase and as output, generates a square matrix, question by question (dimensions 19×19 for 2014; 22×22 for 2017), where each element in row i of column j corresponds to the conditional entropy of question q_j , since question q_i is known. Data was normalized by Min-max normalisation⁵ [9], since the values were very close to each other. The diagonals were taken as 1.

(b)Graph construction: the conditional entropy matrix was taken as an adjacency matrix to construct a directed graph with the objective of simplifying the visualisation of dependencies. Each node of the graph represents a question and each relationship weight represents the conditional entropy between them.

(c)Node filtering: we select the questions with the highest entropy values (between 0.99 and 1). This prevents possible bias in our analysis generated by extremely easy or extremely difficult questions, given that the resulting questions have approximately 50% chance of success; therefore, they can't be considered easy (it's already known that the

⁴This equation can be decomposed into equation $H(X|Y) = - \sum_{y \in \gamma} \sum_{x \in \chi} p(x, y) \log p(x|y)$, which is the one used in the methodology.

⁵Min-max normalisation is given by $x' = \frac{x - \min(x)}{\max(x) - \min(x)}$.

vast majority of students are going to score) or difficult (it's known that the vast majority of students are going to get it wrong). For 2014, questions 10 and 13 were not included since they only relate to one question each, being isolated from the others. In 2017, there were questions with high entropy not selected because we also apply a relationship filter, to be discussed next.

(d)Relationship filtering: a filter was applied to remove the relationships holding the lowest conditional entropy values (between 0.4 and 0). Thus, we are asserting the force of the influence that the random variable Y exerts on X . For instance, the question X solely holds an entropy close to 1. But its entropy is close to 0 after question Y is known, even when the latter question has exactly the same profile as question X . The final graph only contains high entropy nodes and low conditional entropy relationships.

Table 1: Advantage quantification per question from the 2014 edition. The highest gains are highlighted in yellow.

5. RESULTS AND DISCUSSION

Our results show that the two 2014 and 2017 ENADE editions presented groups of highly connected questions from strongly related areas of knowledge. In both cases, the conditional entropy allowed us to highlight the underlying dependence structures of the curricular components behind the questions. Such structures can be represented by a graph, in which the questions are the nodes and the edges indicate the dependence relationships.

Figure 1a depicts the resulting graph based on the 2014 edition of ENADE. You will see that questions 11, 15, 24, 25, 27, 28 and 32 are nearly all directly or indirectly related to

Figure 1: Graphs for 2014 and 2017 ENADE editions.

the area of Software Engineering, the only exceptions being questions 11, 15, and 28. Question 11 is about Probability and Statistics, but is quite intuitive, demanding only logical reasoning, while the question background still relies on software operation. Besides, this question has more influence on the others than the opposite. Question 15 is about Fundamentals of Systems and Databases, requiring awareness of differences between Online Transaction Processing and Online Analytical Processing systems subject (very related to Software Engineering). Finally, Human-computer interaction is the main subject of question 28, addressing Usability with Software Requirements Specification (strongly dependent on Software Engineering). We may therefore conclude that our methodology was able to identify the questions in the 2014 ENADE edition that require knowledge and competences related to Software Engineering.

In order to highlight the importance of the dependence relationships, Table 1 describes, for each edge of the graph in Figure 1a, the percentage of advantage gain (G) for scoring a question, given the correct answer of another. This measure consists of the percentage of the conditional probability $P(X|Y)$ over the prior $P(X)$. As one should note, question 27 influences the largest number of questions (a total of 5) and also provides the greatest advantage gains (a total of 3) for many questions. As a result, students who correctly answer these questions are more likely to get, at least, three other questions right. Undoubtedly, there are underlying relationships that tie question 27 to the others. This leads us to support the hypothesis of bias in the students' responses, favouring the area of Software Engineering and the ones closely related.

The same scenario can be clearly verified in the 2017 edition. Consequently, there is also a group of interconnected questions with very close contents. Note that questions 19, 23, 26, 27, 30 and 35 are all highly associated to Software Development area, even though questions 19 and 27 are not directly connected to it. The content behind question 19 is Graph theory and its area of knowledge is Operations research, a discipline that deals with the application of advanced analytical methods to solve problems and help to make better decisions. Although this is a mathematical approach, this area is still very tied to programming (the programming area is one of the essential bases in Software Development); Question 27 is about Knowledge management, yet the question addresses the use of Tacit and Explicit Knowledge in the different phases of Software Development.

Similarly to Table 1, Table 2 was reproduced for the 2017 edition graph. It reports the influence of questions 26, 27 and 35 on each other, and on others quite clear. Scoring question 35 leads to higher chances of scoring 26, which in turn increases the chances of correctly answering questions 23 and 19; and question 27, brings an advantage for scoring questions 19 and 30. Overall, by answering question 35 correctly, there will be four other questions more likely to score. Thus, we believe that there is also a bias in the 2017 edition, favouring Information Systems programmes, or student profiles, with focus on Software Development.

6. CONCLUSIONS

Our methodology has successfully identified potential knowledge dependence structures through mutual information between questions. The adoption of information measures has proven to be very helpful, providing good level of interpretation to reveal underlying dependence structures. However, a limitation of our work is to deal with deeper and more complex underlying structures, which require multilevel analyses and different strategies to visualize and evaluate relationships between questions.

ABSTRACT

Most formal educational practices based on the classroom, imparts skills and knowledge at scale, by adopting the model of a *factory*. Here, the focus is on creation of formal processes, mass production of measurable outcomes, and standardization. Curricula and educational practices are designed for a hypothetical “average” student, having “average” abilities. However, recent advances in individualization have found vast discrepancies between individual traits and group averages. Designing models based on group averages, are usually ineffective when the *individual* is the target beneficiary. This research proposes *Evidence Based Competency Model* as a mechanism for providing individualized learning experiences. Here, the term *evidence*, refers to informal data generated by the learner, pertinent to the learning process. Individual models are built for each learner, based on their learning activities. These models are clustered to observe similarity in learning patterns among the individual learners. This study also shows significant variability from the “average model”, validating *The Myth of Average*.

Keywords

Evidence, Average Model, Individualization, Evidence Based Competency Model, Learning Process

1. INTRODUCTION

The objective of education is to create empowered individuals that are capable of problem solving, upholding their individuality, and possessing an ability to acquire relevant competencies in their area of interests. Standardization of learning practices based on the classroom, has lead to uniform teaching and assessment practices without regard to how disparate individuals behave, learn, develop and apply their knowledge.

The classroom model is able to provide pedagogical solutions at scale by addressing the needs of a hypothetical “average” individual. However, research on individualization

have shown that, as the number of dimensions of concern increase, the probability of finding an individual who is average on all dimensions rapidly diminishes to zero. This is popularly called *The Myth of the Average* [1]. A uniform model based on statistical averages does not capture the patterns of variability among individual learners [2]. Each individual has different interests, disposition, contexts and styles to learn different topics.

One of the emerging approaches towards standardizing pedagogy models, is to focus on *learning outcomes*. The Outcome Based Education (OBE) [3] model focuses on learner’s ability to produce specific, measurable outcomes as part of the learning process. The emphasis on visible outcomes, discounts the holistic nature of education comprising of a number of tacit elements and OBE is also considered to be strongly rooted in behaviorist learning practices, that are incompatible with other learning cultures like constructivist education [4].

In this work, we show that data generated during the learning process, referred to as *evidence*, can be used to reason about the underlying competency. We also show that one single average model to predict the state of the competency cannot be used and we need to build separate models for learners, hence validating the Myth of Average, discussed in more detail, in [5].

The use of activity data, rather than assessments and outcomes, for determining learner’s latent competency levels, have been addressed for specific activities in [6, 7]. The focus here has been to correlate different types of learning activities like watching video or learning by doing activities, to their implication on learning [8].

In this work, we don’t focus on any specific learning activity and follow a generic approach to collect any kind of learning data and use machine learning techniques to correlate characteristics of activity data with data from outcomes and formal assessments. We focus on activities involving learners consuming resources like videos, text books, articles, documents in the current implementation of the model.

2. EVIDENCE MODELING

The term “evidence” is contrasted with “outcomes” as follows: outcomes refer to assessment data collected from formal testing environments, where the learner is fully cognizant of being assessed and has explicitly prepared for the

Praseeda, Srinath Srinivasa and Prasad Ram "Validating the Myth of Average through Evidences" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 631 - 634

same. In contrast, evidence pertains to data collected on an implicit, continuous basis on any activity of the learner pertaining to the competency in question. Existing methods of determining the underlying competency of a learner through formal assessments and visible outcomes, has its own issues [3, 4]. There is a need for models that uses evidences, based on the learner’s activities and maps these learners to their competencies.

We propose a model that explores the activity data of the learners, generated while achieving the competency. The data, collected implicitly in a continuous fashion, is modeled to map the learners to their competencies.

Evidences can be considered analogous to an observation that an individual makes, in the classroom through interaction or silent observation of reactions, which contains significant insights. An offline system like a classroom is unable to gather data for each individual during the learning process, but when learning happens in a Technology Assisted Learning Environment (TALE) [9], data is continuously captured by the platform. Technology augmentation can happen in various ways – like sensors and RFID tags to record attendance, recording and analysis of students’ classroom activities like questions, discussions, etc. We want to focus on the evidences, so that we don’t have to rely only on the formal assessments to determine the competency of the learner.

A competency model based on evidences can also be used to identify anomalous cases where the outcomes state that the individual has the competency while the evidence indicates a lack of competency, or vice-versa. A teacher can only analyze such cases and address them appropriately. The model based on evidences, acts as a way of aiding the teacher in teaching and evaluating process.

Newer learning domains like training drivers to learn a particular language that would improve their communication skills, may not have standardized competency models to aid in pedagogy and assessments. In such cases, models based on evidences would help to map the learners to their competencies.

The main challenge is to create an evidence model for collecting data, and to argue for the completeness of the evidence. Learning may happen outside of the evidence gathering, and different kinds of learning activities may require different kinds of evidences to reason about them.

In order to address the above challenge, we adopt a least-biased model for evidence modeling, and treat each form of evidence as equally important in the input feature vector. All forms of evidences collected are then given as input to a machine learning algorithm to find the best possible indicators for the outcomes based on assessment scores.

3. EXPERIMENTS AND INITIAL RESULTS

The activity data used to build models is collected from a large, open online learning platform, implemented across several schools in the US, *Gooru.org*¹. The platform has aggregated open learning resources for various courses, pro-

vided by content creators, curators and instructors. The learning resource can be a document, video, audio, puzzles or any content used to obtain the competency. Learners enroll to various courses.

A course is organized into several competencies, where a competency is seen as the basic unit of learning. Each competency may have several learning resources mapped to it. Students consume learning resources and whenever they are ready, give assessments to earn a score. Instructors evaluate the assessments and provide their feedback in the form of scores. The scores indicate the status of the learner with respect to the competency. The learning resources are mapped to competencies for various courses like Maths, Science, English and Social Science in the K-12 curriculum².

The activity data collected for a (learner, competency) pair, is divided into collections and assessments. Collections are resources used during the learning process, while assessments act as indicators of learning. In the platform, a learner is said to have achieved a “completed” status for a competency if one gets more than 80% in the respective assessments. The platform does not award a “fail” status to the learner. The learner keeps attempting assessments multiple times until the learner gets 80% or more. The status is then set to “completed”, else the status is marked as “in-progress”.

Whenever a learner consumes a resource to learn a concept, an event is logged in the system with the details of the resource, time of the event, learner details and type of event (started consuming the resource). The same process is repeated when the learner finishes consuming the resource with a stop event. The events are captured for all the courses. Individuals consume various resources mapped to the same competency and at the end give assessments to get a particular status for that competency.

Using these activity data we have built a model to determine the outcome of the competency based on the evidences.

3.1 Experiment 1

We built a Support Vector Machine (SVM) [10] classifier to test a hypothesis. Our hypothesis is as follows: H_t : *The time spent on learning resources, the total number of resources consumed by learners, can predict the outcome for the underlying competency.*

The features identified are total time spent on resources, average time spent on resources and number of resources used for acquiring the corresponding competency. The users were given a completed or in-progress status based on their assessment scores. That serves as the ground truth for our model.

The dataset has 28000 (user, competency) pairs with their corresponding evidences. This data was divided into 80-20 split randomly for training and testing the SVM model respectively. We built a single SVM model for all learners and their competencies in all courses. We classified the data using linear, polynomial, sigmoid and radial basis kernel function. The data was not linearly separable. The radial basis

¹<http://gooru.org/>

²<https://en.wikipedia.org/wiki/K-12/>

kernel function was found to be the best kernel function to classify the data in terms of Accuracy, Precision and F1 score as shown in Table 1.

Kernel functions	Accuracy	Precision	F1 score
Radial basis	82.43%	68.79%	51.13%
Linear	78.39%	53.65%	40.30%
Polynomial	78.83%	56.25%	37.91%
Sigmoid	68.84%	30.68%	30.37%

Table 1: Performance metrics comparing the kernels

The accuracy measure of the SVM model using the radial basis function states that using total time spent, average time spent on the resources and number of resources, we can significantly predict the outcome of the underlying competency. The outcomes are determined by the scores of the assessments, which was not used as feature to build the models. This shows that evidence can be used as an alternate way to model the outcome of the underlying competency.

The same model was made to classify all the competencies of a random individual learner, the accuracy of the average SVM model varied between 30% to 100% for different learners. The “average learner” model computed above, was not effective in determining the outcome of a competency of an individual learner. This indicates that we cannot use one single aggregated model on all individuals. Models must consider personalization i.e., we need to build individual models for each users and aggregate the models based on common properties.

To do this, we require significant amount of data for each learner. So, instead of aggregating time spent on resources at a competency level as total time, we looked at time spent for each resource and aggregated the data separately for each learner in the next experiment.

3.2 Experiment 2

In this experiment, we used data from each activity event and modeled the time spent on each resource mapped to a particular competency. Using the start and the stop time, we computed the time spent on each resource and we also observed that some individuals consumed the same resource again. Based on this, we formed our second hypothesis: H_u : *There is a large variance among the individual models built for each learner based on their learning activity data.*

We wanted to observe the consumption of resources and the time spent on those resources, could predict the outcome of the corresponding competency for that individual learner. We also wanted to observe if the models built for each individual learner had common properties and could be merged to a single model or there is a large variance among them.

The amount of time spent on each resource is stored as a vector for each (learner,competency) pair, the length of the vector is the number of resources and the order of the vector tells the order in which the resources were consumed. The length of the vector varied for each (learner,competency) pair. To build individual learner models and compare them, we require equal number of features for all pairs of (learner, competency).

To achieve this we transformed the time spent on resource vector, to a matrix in the following way. We computed the range of total time spent on (resource,competency) pair by all learners. This value varied from 10 seconds to 46000 seconds. After observing this distribution, we decided to have a time frequency of 100 seconds and computed the cumulative sum of resources consumed by the learner at each frequency i.e. 100th second, 200th second etc. We populated 460 time frequency columns. We arrived at this time frequency value of 100 seconds by dividing the maximum total time and time frequency.

For example, if the learner has consumed 2 resources for a competency code “3”, spending 90 seconds on first resource and 170 seconds on second resource then the column 0(time_100) will have the value 1, column 1(time_200) will have the value 1 as the learner has not finished consuming the second resource by 200 seconds, column 2(time_300) has the value 2 and rest of the columns till column 459(time_460) will have the value 2 indicating that the user consumed maximum 2 resources. Fig. 1, shows the subset of the data passed to the model for a single user, where code refers to competency code and rest of the columns are the evidences for that competency code for a single learner. The row containing code value 3, shows the corresponding result of example mentioned above. The features also includes normalized total time spent on resources and normalized average_time spent on those resources for a particular (competency, learner) pair.

Code	Total_time	Average_time	0	1	2	3	4	5	6	7	...	451	452	453	454	455	456	457	458	459	status
0	0.588666	0.998084	0	0	0	0	0	0	0	0	...	2	2	2	2	2	2	2	2	2	0
1	0.348463	0.128140	0	0	1	1	1	1	1	4	6	...	9	9	9	9	9	9	9	9	0
2	0.000000	0.000000	1	1	1	1	1	1	1	1	...	1	1	1	1	1	1	1	1	1	1
3	0.060333	0.100575	1	1	2	2	2	2	2	2	...	2	2	2	2	2	2	2	2	2	1
4	0.294333	1.000000	0	0	0	0	0	0	0	0	...	1	1	1	1	1	1	1	1	1	1

Figure 1: Data passed to the classifier with cumulative frequency of resources with respect to time, total_time and average_time as features.

SVM model with linear kernel was used to classify the data. Learners who had more than 30 competencies in any course and with any status (completed or in-progress), were selected for analysis. There were 42 learners who satisfied that criteria and individual SVM models were built for those learners. Individual learner’s data was divided into 80-20 split randomly for training and testing respectively. The models for each learner gave an accuracy between 80% to 100%. The accuracy was calculated from the confusion matrix generated for each individual model according to the formula mentioned in ³. Each model generated a coefficient vector of length 462. We also built a single model comprising the activity data all these 42 learners and called this the “average-model”, as detailed in Experiment 1, for comparison.

All the 43 vectors of coefficients for the 43 models populated were clustered using the K-nearest neighbor clustering algorithm⁴ to observe any similarity among these models.

³https://en.wikipedia.org/wiki/Evaluation_of_binary_classifiers

⁴https://en.wikipedia.org/wiki/K-nearest_neighbors_algorithm/

The Euclidean distance between the data points (models) was used as a measure to cluster the models. To find the appropriate number of clusters, Elbow method⁵ was used to find the optimal number of clusters. The summation of distance between that specific cluster against the cluster centroid was computed and plotted for various number of clusters, between 1 and 43 where 43 was the total number of models. The graph in Fig. 2 shows the variance in the sum of the squared distance between clusters against the number of clusters.

Figure 2: Elbow method showing the variance of number of clusters and their distances

Using the variance in the Elbow method, we found the optimal number of clusters to be 6. This says that the 43 models including the average model can be clustered into 6 clusters, and there are some common properties among these models.

Fig. 3 shows the distribution of 43 different models including the average model into 6 different clusters. The blue point refers to individual learner models and the red point indicates the “average learner” model.

Figure 3: Distribution of individual learners models and average model into 6 clusters

We see that the individual models don’t cluster with the average model. For this dataset, the average model does not represent any individual learner. This validates our hypothesis that there is large variance among the individual models built for each learner based on their learning activity data and hence validates “The Myth of the Average”. It also shows that we need not build one model for each individual which would make it extremely difficult to map new

learners to their competencies. We find that there are some common properties among the learners which can be used to find the best model for each learner. We need to determine those common properties in the future and provide better learning experiences to each individual learner.

4. CONCLUSION

We proposed an Evidence Based Competency Model, that uses data generated during the learning process by learners to find the outcome of the competency. The experiments shows that having a single average model can be tuned to get a higher accuracy, but does not represent any individual. This presses the need to consider individual learner’s variance and not rely on statistical averages to map learners to their competencies. This also says that we cannot provide each learner the same learning experience and cannot validate their underlying competencies through uniform evaluation mechanisms like outcomes. This research shows initial results towards that direction.

5. ACKNOWLEDGEMENTS

The authors would like to acknowledge and thank the contributions of the project associates Thrivikram Mudunuri, Juhi Singh, Naman Dosi and Kartik Gupta.

ABSTRACT

Intelligent Tutoring Systems for online learning need to design their cognitive and student models to analyze every student's dynamic knowledge state and factorize the cognitive process for solving each online exercise into the latent skill sets. In this paper, we present the Automatic Temporal Cognitive (ATC) model, a unified and integrated framework to automatically discover a multiple-dimensional cognitive model and formulate a student model over longitudinal student data. This framework enables us to trace the dynamic change of multi-dimensional skills including skill improvement and forgetting for the student learning process. Moreover, based on the framework, we can automatically build the cognitive model through student performance data to describe the latent skill vector (aka Q-matrix) for educational content. Experimental results confirm that our unsupervised approach is better than the traditional method in public datasets.

Keywords

Cognitive model; Student model; ATC framework, Skills dimension determination.

1. INTRODUCTION

Over the past decade, intelligent tutoring becomes increasingly important in online education to offer personalized and adaptive learning experience for massive scale of students. An essential question about building intelligent tutoring systems for online education is how to develop the cognitive model of educational contents and student model from student response data in online education platforms[1]. A typical application scenario is personalized learning path recommendation where an intelligent tutoring system must infer the latent multi-dimensional skill vectors of every student from a temporal sequence of student interactive events. It often needs both cognitive model and student model to trace dynamic change in a student's skill and plan the personalized learning route.

Traditionally, the cognitive model and student model of an intelligent tutoring system must be designed in multiple steps: First, domain experts specify an original cognitive model in the form of Q-Matrix[2, 3] through the process of Cognitive Task Analysis (CTA)[4]. Second, based on the Q-Matrix that specifies the association among latent skills and education contents, researchers

can design the student model using different kinds of modelling frameworks such as IRT[5], Bayesian Knowledge Tracing (BKT)[6]. Third, the parameters of the student model must be fitted with student response data. The above cycle has its limitations because the subjective specification of the Q-matrix may not be reliable and could possibly result in insufficient model fitting and inaccurate estimation of the latent cognitive skills of students.

Recently, data-driven methods have been proposed to automatically or semi-automatically discover the cognitive models. They can be regarded as the further step to validate and refine the expert-designed cognitive model. But current methods for discovering cognitive models are restricted in that they cannot handle longitudinal data. On the other hand, the popular student models such as Item Response Theory (IRT) model and Learning Factors Analysis (LFA)[7] only evaluate student ability at the moment when they take examinations or exercises. They don't consider the dynamic change in student ability with their interactions with education contents. Knowledge Tracing (KT) can model students' changing knowledge state during their skill acquisition process. But the conventional KT model doesn't support multi-dimensional skill model and must work with other algorithms to perform Q-Matrix discovery.

In summary, the existing frameworks for cognitive models and student models are not well integrated to effectively deal with multi-dimensional and longitude learning data generated by personalized online learning systems. In this paper, we propose the Automatic Temporal Cognitive Tracing framework aiming to build the following models from student learning data: (1) dynamic multi-dimensional student model with the forgetting factor (2) multi-dimensional cognitive model. The student model can describe the forgetting factor in the multi-dimensional skill levels during the student learning process. The cognitive model can automatically discover the skill set (aka Q-matrix) that include the latent skill vector for educational content. The ATC framework seamlessly integrates both models and enables us to estimate dynamic student ability and Q-matrix. The major contributions of our paper include:

- (1) **Propose a dynamic student model including students' skill acquisition and skill forgetting.**
- (2) **A fully automatic approach to discovering a cognitive model for educational contents.**

The paper is organized as follows: Section II describes the current research on student model and cognitive model. Section III introduces the automatic temporal cognitive framework in detail. In section IV, we introduce the datasets for experiments. Section V shows experimental results in different datasets and situations. Finally, sections VI gives the conclusion and discusses future work.

2. RELATED WORK

2.1 Conjunctive Factor Model and Automatic Cognitive Analysis

Researchers have introduced performance factor analysis models such as Conjunctive Factor Model(CFM) [7] to build student model and support automatic cognitive discovery[8]. CFM is essentially a parametric IRT model to model the item responses given the latent Q-Matrix. Eq(1) defines the probability for student i to get item j right, where θ_i represents coefficient for proficiency of student i , β is skill difficulty coefficient vector, γ is skill learning rate coefficient vector and T_{ik} is the number of practice opportunities for student i to learn the skill k .

$$p_{ij} = \Pr(Y_{ij} = 1 | \theta_i, \beta, \gamma) = \prod_{k=1}^K \left(\frac{e^{\theta_i + \beta_k + \gamma_k T_{ik}}}{1 + e^{\theta_i + \beta_k + \gamma_k T_{ik}}} \right)^{q_{jk}} \quad (1)$$

The Q-Matrix in the CFM model has to be explicitly defined before it can be fitted in learning data. To extend the capability of the CFM, Matsuda[8] introduces a machine learning workflow for automatic discovery of skill models from online course data. The framework consists of three major steps: feature extraction, cognitive skill model construction and model search. The step of feature extraction attempts to calculate a candidate Q-matrix using a combination of NMF and K-means clustering method. The step of model construction and model search work together to make further exploration on the skill dimension and find the best Q-matrix and student model at the same time. The step of model construction proposes new Q-matrix candidate by splitting and merging skills in the initial Q-matrix, and the step of model search tries to fit the data with the Q-matrix candidate and student model in the form of CFM or other model families.

The enhanced CFM model with cognitive discovery still has its limitation. As an extension of classic IRT model, the CFM model doesn't describe the dynamic change of the student proficiency. Although its parameters contain the skill learn rate, it doesn't explicitly model the improvement of a student's skill vectors or the forgetting factor in his learning process.

2.2 Knowledge Tracing and Multiple-Skill Extension

Bayesian Knowledge tracing (BKT) was presented by Corbett and Anderson [6]; it uses a Hidden Markov Model (HMM) to track students' knowledge states over time. It divides the target knowledge into several skills, and each skill designs several assessments. But an issue with the conventional BKT model is that it can only track student mastery of single cognitive skill and doesn't support assessment of item difficulty.

Recent research development on BKT models focus on multiple-Subskill Extension in BKT modelling. Brenes[9] extended the KT

model and proposed Dynamic Cognitive Tracing which is a fully automatic approach to discover a cognitive model and student model of longitudinal student data. In his later work, Gonzalez-Brenes proposed Feature-Aware Student Knowledge Tracing (FAST)[10] to incorporate different skill features, such as subskills, problem's difficulty and student ability as parameters in KT model. Each parameter could be expressed in logistic regression for modeling the guessing and slipping probability with the skill features. Similarly, Yanbo[11] restructures the classic KT model using logistic regression over each step's subskills to model the transition probability including learning and forgetting for overall knowledge required by the step. All these feature-based extensions of BKT must rely upon experts to predefine the skill and subskill features without providing any automatic Q-matrix discovery method.

2.3 Item response theory

Item Response Theory (IRT) is a framework for modeling student responses on a set of assessments. The model is used to describe the relationship between the proficiency of a student and the likelihood of correctly answering a test item. It assumes that student proficiency is invariable in a test, and all the test items are measuring the same potential trait. In the two-parameter IRT model, the probability of the student s correctly answering the question q is given by:

$$p_{sq} = f(\alpha_q(\theta_s - \beta_q)) \quad (2)$$

We selected $f(x) = \Phi(x)$, where $\Phi(x)$ is the cumulative distribution function of the standard normal distribution. This model is known as the two-parameter ogive model.

Despite of the recent progress in the research of cognitive modeling for ITS, most modeling frameworks haven't presented an integrated and automatic solution that can tackle with the longitude student data and accurately describe the temporal development of individual students. **TABLE I** summarizes the status of the major proposals in the research community.

The major objective of the ATC framework is to present a unified modelling framework to address the above issue. From **TABLE I**, one can see the framework incorporates multi-dimensional and dynamic skill vector as well as the potential forgetting factor in the extended IRT system to describe the temporal learning sequence from student interaction events with educational contents. Moreover, the ATC employs the CFM model and Bayesian optimization to quickly identify the dimension range of latent skills, and perform its own IRT based statistical inference to calculate the optimal skill vectors.

TABLE I Comparison among CFM, KT, CDM and ATC framework

	Multi-Dimension Skill	Temporal Skill Development	Modeling Forgetting Factor	Automatic Q-Matrix Discovery and Refinement
CFM	Yes	Yes	No	No
Knowledge Tracing	Yes	Yes	Yes	No
CDM	Yes	No	No	Yes, Statistical Inference
ATC with IRT	Yes	Yes	Yes	Yes, Dimension Discovery + Statistical Inference

3. Automatic Temporal Cognitive Framework

The ATC framework presents a temporal probabilistic model describes dynamic student multi-dimensional skill level and the skills required for educational contents. Eq(3-4) represent the IRT function based skill embedding that projects a vector of multiple-dimensional latent skills into the a specific exercise:

$$q_{sit} = \frac{\vec{\theta}_{st} \cdot \vec{a}_i}{\|\vec{a}_i\|} - \|\vec{a}_i\| \quad (3)$$

$$p_{sit} = Pr(R_{sit} = 1 | \vec{\theta}_{st}, \vec{l}_i, \vec{a}_i) = \phi(q_{sit}) \quad (4)$$

Where

- ϕ is the logistic function convert a value to a probability between zero and one.
- $\vec{\theta}_{st}$ is the vector which represents the ability of each skill of student s at the timestep t .
- \vec{a}_i is the vector which represents the required skill level of exercise i .
- \vec{l}_i is the vector that represents the ability augmenter that a student can obtain after finishing question or education content i .
- R_{sit} is the result of the response of student s on question i of the timestep t .
- p_{sit} is the probability of the student s has a correct response on exercise i at timestep t .

According to Eq(3) and (4), the probability that the student s gives a correct response to the exercise i depends upon his ability $\vec{\theta}$ and the exercise's required skill level \vec{a} . We selected an exercise which requires two skills to plot the relationship between the student ability vector ($\vec{\theta}_s$) and the probability of correct response (p_{sit}). Figure 1 shows that the probability of correct response increases along with an increase in each element of the student ability vector. The figure also shows that the probability increases more quickly with changes in location parallel to the skill2-axis than changes parallel to the skill1-axis. The different increase rate corresponds to the difference in the \vec{a}_i parameters.

Figure 1 Probability of correct response for an exercise with given \vec{a}_i ($a_1 = 0.447$, $a_2 = 1.459$)

Eq(5-7) define a nonlinear dynamic system for hidden learning states of every student. They capture the temporal change between consecutive learning states and the skill improvement factor as well as the forgetting factor:

$$\theta_{s(t+1),n} \sim N(\mu_{s(t+1),n}, \sigma^2) \quad (5)$$

$$\mu_{s(t+1),n} = (\theta_{st,n} + l_{i,n} * \phi(q_{sit})) * f_{st,n} \quad (6)$$

$$f_{st,n} = \exp \left\{ - \left[\frac{1}{1 + \theta_{st,n}} * r + \beta \right] * \Delta t \right\} \quad (7)$$

- $\theta_{st,n}$ means the able of the n -th skill in the dimension of $\vec{\theta}_{st}$.
- $l_{i,n}$ represents the value of the n -th dimension of the vector \vec{l}_i .
- r and β are two parameters to fit.
- $f_{st,n}$ is the forget coefficient of student s from timestep t to timestep $t+1$.
- Δt is the interval between timestep t and timestep $t+1$.

Eq(5) assumes that latent skill $\theta_{s(t+1),n}$ at the moment $t+1$ follows the gaussian distribution with the mean $\mu_{s(t+1),n}$ depending upon the nonlinear transformation of $\theta_{st,n}$ on the previous moment. Eq(6-7) defines the transformation function that describes both knowledge acquisition and exponential forgetting factor in student learning process over the problem-answering sequence. Eq(7) indicates the forget coefficient is primarily determined by the current skill level of the student s and the time interval between two adjacent problem-answering events.

We estimated the model parameters for the ATC model by maximizing the following objective function:

$$L(\omega) = \text{Log Likelihood} = \sum_s \sum_{T_s} \log P(R | \vec{\theta}_{st}, \vec{l}_i, \vec{a}_i, \vec{f}_{st}) \quad (8)$$

Where ω is the model parameters, \mathcal{S} is the collection of all the students, T_s is the collection of all the answer timesteps of student s . We use Stan[12] to quickly implement a prototype of the ATC model. Stan is a state-of-the-art platform for statistical modeling and high-performance statistical computation. It's easy to specify log density functions in Stan's probabilistic programming language. Given the nonlinear nature of the ATC model, it is impossible to utilize EM method which is commonly used for linear space state models. Therefore, we employed HMC (Hamiltonian Monte Carlo) sampling in training the parameters of the ATC model according to the maximum likelihood goal.

4. Experiments

In our experiments, we choose area under the ROC curve (AUC) as the performance metric to measure the discriminative ability of the student model. Our experiments compared the following models:

- Model A: Non-negative Matrix Factorization and Conjunctive Factor Model (CFM). We combine both models to predict the probability of correct answer.
- Model B: ATC model without temporal skill improvement and forgetting factor.
- Model C: ATC model without the forgetting factor.

The experiments include two public datasets[13] and one simulated dataset. The public dataset was collected from Open Learning Initiative online course of biology from 2012 to 2014 include 5186 students and 4831 unique steps. We select chapter Cells and Gene from the entire dataset.

- 1) Dataset Cells: selected from chapter Cells and Chromosomes includes 68 students and 34 questions.
- 2) Dataset Gene: selected from chapter Gene Expression includes 99 students and 27 questions.
- 3) Simulated dataset: simulated data generated by model B

TABLE II Prediction performance of ATC and other models

Models	Dataset Cells		Dataset Gene	
	AUC	Loglikelihood	AUC	Loglikelihood
Model A	0.830	-347.664	0.662	-335.666
Model B	0.742	-1594.142	0.270	-1162.372
Model C	0.753	-9199.437	0.867	-4897.249
ATC model	0.872	-2902.272	0.793	-2322.128

4.1 Comparison of different models

The experimental results on the public datasets are summarized in TABLE II. It shows that the ATC model achieves the best AUC performance and its AUC is 17% higher than that of Model B in the dataset Cell. Model C achieves the best AUC and its AUC is 18.8% higher than that of Model B in the dataset Gene. It should be noted that the Model C without forgetting factor demonstrates better performance than the ATC model in the dataset Gene. We compared the total interval of two dataset and found that the datasets Gene has a shorter interval in the problem-answering sequence. The difference in the studying interval may contribute to the strength of the impact of the forgetting factor, which could explain why the ATC has slightly worse performance than Model C. Moreover, the Model A with the combination of Non-negative Matrix Factorization and CFM has worse performance than our ATC model in both datasets.

4.2 Comparison in different amount of data

We compare the performance of our model in different data sizes with a changing sequence length and student number with the ATC model. Based on the dataset Cell, we run two groups of experiments: (1) In the first group of experiments, we change the sequence length of every student and keep the constant number of students. We choose seven datasets with the data size ranging from 800 to 2800 (under the same student number). (2) In the second group of experiments, we increase the number of student and keep the sequence length unchanged. We choose six datasets with the student number ranging from 20 to 70.

Figure 2 plots both experimental results. One can see that the AUC performance has an increasing tendency with the increase in the sequence length. It usually means that a longer problem-answering sequence can demonstrate dynamic of students' skill in a more accurate way. Furthermore, the increase in student number may slightly affect the performance of the ATC model and in some cases, it may even lead to degrade in the AUC performance.

These findings suggest further investigation should be made about the robustness of the ATC model on different lengths of problem-solving sequences and student number. Note that both factors can increase the number of parameters in the ATC model to be trained. Thus, more training experiments are needed to avoid possible overfitting or underfitting for the increase in complexity of the ATC model. Currently, the HMC process of training the ATC model is slow due to the large number of the model parameters. We are studying more efficient model training method for the ATC model to make sure that the model can be comprehensively evaluated in different datasets.

CONCLUSION

In this paper, we propose an Automatic Temporal Cognitive model

**Figure 2 AUC of the ATC model**

to trace student dynamic multidimensional ability and determine the related skill sets for educational contents in personalized learning system. This model regards the cognitive Q-Matrix as part of the model parameters and introduces nonlinear transmission functions to define student skill augmentation and forgetting factor. Experimental results confirm that our ATC approach is better than the traditional methods such as the combination of Non-negative Matrix Factorization and CFM. Moreover, the ATC model with skill improvement and forgetting factors tend to outperform the same multidimensional baseline model without these new features.

ABSTRACT

This paper investigates the potential of using an automated system for capturing students' body postures, location, and gestures in a makerspace as a means to quantify their affective states. In this study, Kinect sensors captured students' behavior in a fabrication lab over period of a 13-weeks semester, recording nearly half a million observations from 16 students enrolled in a class. Weekly surveys were conducted to serve as a ground truth for the students' affective states. Results from the survey were then analyzed in conjunction with the Kinect data to validate the setup of an automated system. Our preliminary findings suggest that our multi-sensor system is able to make a first step toward estimating students' levels of challenge, engagement and frustration. We conclude by describing how this kind of automated system provides a promising methodology for instrumenting makerspaces and supporting student learning in open-ended learning environments.

Keywords

Makerspaces, Open-ended Learning Environment, Instrumentation, Learning Analytics, Monitoring Tools

1. INTRODUCTION

Over the last decade makerspaces have garnered a great deal of attention given their potential for student's success in STEAM (Science, Technology, Engineering, Arts, and Mathematics) education [5]. The open environment, digital fabrication tools, and the community aspect of these spaces result in cultivating a growth mindset and creativity, which are often more effective than traditional learning experiences. Makerspaces typically involve person-to-person interactions and discussions throughout the development of an idea, design, and implementation, along with learning about modern tools such as 3D printers. More important from an educational perspective, those spaces support the development of important 21st skills such as problem solving and critical thinking.

A challenge within these largely open-ended learning environments, however, is the ability to measure those skills

Lucia Ramirez, William Yao, Edwin Chng, Iulian Radu and Bertrand Schneider "Toward Instrumenting Makerspaces: Using Motion Sensors to Capture Students' Affective States in Open-Ended Learning Environments" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 639 - 642

quantitatively and assess the effectiveness of pedagogical practices. A nascent field of research, Multimodal Learning Analytics (MMLA; [3]), proposes to use multimodal sensors to capture fine-grained information about students' learning trajectories. The ability to capture and track student behaviors can: 1) lead to a better understanding of the development of these skills; 2) inform instructors and facilitators of student's behavioral performance; 3) provide students with formative assessments; and 4) overall, discover new ways of supporting students' learning in open-ended learning environments.

2. RELATED WORK

In this section, we provide a rationale for studying the affective states of challenge, engagement and frustration from the perspective of Flow Theory and review related work on Multimodal Learning Analytics.

2.1 Flow Theory

Csikszentmihalyi (1990)'s flow theory [6] matches skill level of students and given challenge of tasks in order to reveal the affective states of students during their learning.

Since instructors would naturally avoid low challenge tasks that will not add value to students' learning, the concerned affective states for our study would only include flow and frustration. Flow is a multi-faceted construct that includes factors such as high levels of student engagement and distortions in the experience of time. The detection of engagement and frustration could be accomplished relatively straightforwardly using sensors that read body language and facial expression, but the recognition of flow state by sensors require further work that goes beyond the intended scope of this study. Therefore, for the purpose of this study, student engagement is employed as a crude approximation for flow, and student frustration is studied to inform instances when the challenge of the assigned tasks reaches above the skill level of the students.

2.2 Multimodal Learning Analytics

Over the last decade, the rise of the Maker Movement has motivated much research towards understanding the effectiveness and benefits of incorporating "making" activities in education. As research within these complex learning spaces continues, the approach of data collection is shifting from manual observation to more automated methods enabled by technological advancements and capabilities such as multimodal sensing capabilities.

The field of Multimodal Learning Analytics [3] has gained popularity over the last decade as a way to identify meaningful

metrics (or multimodal cues; [4]), that can be leveraged to deepen our understandings of students' states in such environments. Currently, most of MMLA research has been applied within a computerized learning context, controlled experiments (i.e., Randomized Control Trials; [1]) or formal learning environments (i.e., classrooms). For example, in a hands-on learning activity, Schneider & Blikstein (2015) used unsupervised machine learning algorithms on Kinect data and identified prototypical body postures indicating cycles of cognition and action - which were positively correlated with participants learning gains [9]. Using non-invasive methods, such as the Kinect sensor, to track a person's motion allows for practical implementation of assessing individuals' affective states, while preserving a natural environment.

Given that non-verbal cues such as body postures hold important information about mental states [8], this could allow motion tracking sensors to analyze students' affective states, such as perceived challenge of the tasks, levels of engagement and frustration. To our knowledge, the fusion of MMLA and the makerspace development is currently underexplored.

3. OVERVIEW

3.1 Course Curriculum

Over the course of fifteen weeks, the research team collected motion sensor data and survey responses of sixteen graduate students enrolled in a hands-on digital fabrication course. The course aimed to teach students the usage of modern fabrication technologies and their application to educational contexts. Students were responsible for implementing prototyping designs and building educational toolkits with the use these fabrication tools and associated software. Students were tasked with weekly assignments, either independently or in pairs, and asked to record their experiences after each assignment in a weekly survey.

3.2 Makerspace Setup

The makerspace was equipped with two Kinect v2 sensors to capture human motion within the space. The sensors were placed on opposing ends of the makerspace lab. Both sensors were connected to a Django server, where the Kinect data was stored.

3.3 Research Questions

- **RQ1:** At the group level, does this system accurately measure the levels of challenge, engagement and frustration of the class in the makerspace?
- **RQ2:** Can we detect individuals' levels of challenge, engagement, and frustration using the Kinect data?

4. METHODS

4.1 Survey Data

The survey data provides a ground truth to our analysis. In defining the survey, we leveraged prior studies conducted on interactions and learning in makerspaces, as well as surveys used by schools, universities and public libraries to assess the impact of making on students' learning. Making in fabrication labs has been described as offering "visceral design experiences", allowing for unprecedented levels of frustration, engagement and excitement experienced by students [2]. Thus, understanding participants' level of frustration, challenge, or even enjoyment of making assignments is key to validating such claims.

4.2 Kinect Data

We used two Kinect sensors to collect motion and posture data in the makerspace. Motion detection and tracking was possible by the embedded IR sensor within each Kinect sensors. For this study, the collected Kinect data included upper limb joints and binary values (e.g. left hand raised).

Cleaning and Labeling Kinect Data: In order to explore levels of frustration and engagement for an individual (RQ2), we needed to label the bodies in the room with the corresponding student. We collected face images generated by the Kinect sensors to solve the issue of person re-identification. To accomplish this labeling, we used an open-source face recognition algorithm: OpenFace, which produced an accuracy of 88% on average.

Standardizing the Kinect Data: The first step of pre-processing the joint data was to translate all 3-dimensional coordinate points to a reference system. Further data cleaning was facilitated using a video generation script that rendered videos of the makerspace next to a top-down mapping of the makerspace (Fig. 1).

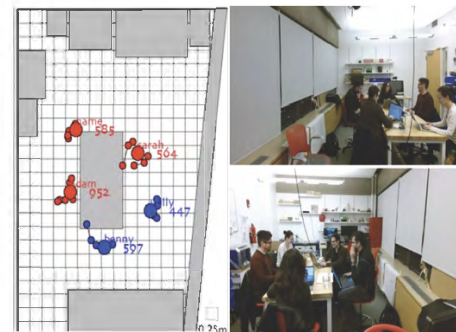

Figure 1. View of Kinect skeletons in space

Deduplicating the Kinect Data: Further data pre-processing consisted of deduplicating skeletons referencing the same person in the makerspace. Detecting duplicates was accomplished by finding head joint overlap within a given timeframe. The duplicate skeletons were then averaged or discarded given the similarity of the skeletons and location in respect to the Kinect sensors.

Generating features from the Kinect Data: Building on prior work [1; 7], we generated features from the Kinect data to capture students' levels of challenge, engagement and frustration. Based on the relative positioning of each skeletal joint, it is possible to generate meaningful features that can provide us with a basic understanding of the participants' body language (see Table 1):

Table 1. A few exemplar features generated from Kinect Data

Features	No. of features	Description
Joint Movement	7	Average of joint displacement between timeframes
Joint Angles	4	Average of joint angle
Lean	2	Average of body lean. Lean Left/Right or toward (forward) / away (back) from Kinect #1
Self - Touch	8	Average proximity between different joints vs. head; and joints vs. hand

In summary, the overall approach involved 1) collecting and cleaning the Kinect data, 2) generating features from skeletal joints,

3) detecting body language using features, and 4) mapping affective states of students.

5. RESULTS

RQ1: Can we detect levels of challenge, engagement and frustration of the class?

Fig. 2 shows a summary of the survey responses over all weeks, which indicates a parallel trend between levels of challenge and frustration, while levels of engagement consistently over a rating of 4. Because there seems to be a ceiling effect on the engagement measure, we focus on the detecting levels of frustration and challenge. Levels of challenge and frustration were very similar to each other (Fig. 2), which suggests that students experienced both at the same time. After generating correlation matrices between the survey and Kinect data, our results show that levels of challenge and frustration are highly correlated with body leaning and certain self-touch metrics (Fig. 3). On the other hand, aggregate levels of engagement did not show significant correlations with any of the generated Kinect metrics.

Figure 2. Survey summary of aggregate levels of engagement, challenge, and frustration

Figure 3. Survey and Kinect data showing that levels of engagement, challenge, and frustration are significantly correlated with self-touch metrics * $p \leq 0.01$; ** $p \leq 0.001$.

In order to further determine the key Kinect features that are associated with levels of challenge, engagement and frustration, we used decision trees to find the optimal combination of predictors. We focus on students' levels of frustration, since it overlaps with levels of challenge, and engagement suffered from a ceiling effect. We split the dataset into four quartiles and use a decision tree classifier to predict if the class was not frustrated (1st quartile), somewhat frustrated (2nd quartile), mildly frustrated (3rd quartile) or highly frustrated (4th quartile). Fig. 4 shows the resulting decision tree:

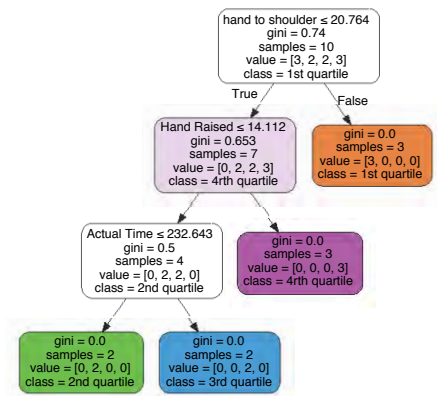

Figure 4: A decision tree used to predict levels of frustration.

Not surprisingly, the classifier is able to perfectly predict levels of frustration for each week of the semester. What interests us, however, is which combination of features is used to make this prediction. As found above, “hand to shoulder” was able to separate the 1st quartile (no frustration) from the other quartiles. “Hand raised” separated the 4th quartile (high frustration) from the other quartiles. Finally, the time spent in the makerspace separated the 2nd and the 3rd quartiles (somewhat / mildly frustrated).

RQ2: Can we detect levels of challenge, engagement and frustration of individual students?

The quantification of this metric is similar to that of RQ1, however, rather than aggregate measures, individual measures were analyzed after we identified Kinect data using a face recognition algorithm. Table 3 describes significant correlations between survey responses and Kinect metrics (defined in Table 1) for each individual. Table 3 shows that students express levels of engagement, frustration and challenge differently, and Table 2 summarizes the patterns found in Table 3. While some of these indicators are overall positively correlated with our dependent measures (e.g., hand movement / agitation, time spent in the makerspace) or negatively correlated with them (e.g., head to elbow, head to shoulder, head to hand), other indicators can be negatively correlated for some students and positively correlated for others (for example, shoulder angle is positively associated with frustration for Zoe and negatively correlated with frustration for Ann).

Table 2. Summary of correlation patterns found between individuals

	Positive	Negative
Challenge	Total time spent in the space, elbow and shoulder agitation, hand-to-elbow pose, and body leaning	Shoulder angle, head-to-elbow, head-to-shoulder, and head-to-hand
Frustration	Raising the hand	Head-to-elbow and elbow angle
Engagement	Hand agitation and raising the hand	Body leaning

Table 3. Cells show significant correlations for levels of frustration (F), challenge (C) and engagement (E) for every student. Orange: Students who expressed mid to high levels in F & C, but shared low levels of E; Red: Students who expressed high levels in all F, C & E.

6. DISCUSSION

Our data indicates that the use of motion sensors can potentially capture affective states in open-ended learning environments. Our findings provide some initial evidence that high correlation between levels of challenges and frustration is a signal that the course assignments may be above the skill levels of students; and frustration of the entire class can be approximated using self-touch gestures. Additionally, levels of engagement were high throughout the semester, which is not surprising given the nature of the class. Thus, it was difficult to find indicators of engagement from the Kinect data. Furthermore, these indicators vary across students. In sum, the correlation between the survey measures and the Kinect data suggest that this multi-sensor system can detect key affective states to inform students' learning trajectories within an open-environment such as the makerspace.

Our preliminary findings suggest that our multi-sensor system is able to make a first step toward estimating students' levels of frustration via affective states. Another contribution of this paper is to highlight the role of individual differences when using this kind of monitoring tools. For a multimodal sensor system to be accurate and successful in supporting teachers and students, it has to take into account these individual differences in ways of experiencing the space.

7. CONCLUSION

Because makerspaces have gained so much popularity over the last decade, it is becoming increasingly important to design rigorous ways of studying them. The multi-sensor system described in this paper makes a first step toward an effective semi-automated methodology for instrumenting makerspaces. While these findings rely on simple measures, they pave the way for more complex data collection and data analysis techniques.

The implementation of such multi-sensor systems in open-ended learning spaces has the potential to 1) attain a better understanding of pertinent skill development; 2) provide students with formative assessments; 3) inform instructors and facilitators of student's behavioral performance; and 4) discover new ways of supporting a student's learning overall. As our understanding of a classroom is constantly being redefined, Multimodal Learning Analytics [3] can certainly assist with optimizing the use of these evolving and varied learning environments.

ABSTRACT

Rich streams of fine-grained activity data are generated by many game-based learning environments. These data can be mined unobtrusively to assess student learning and potentially foster tailored feedback and scaffolding. Stealth assessment frameworks are more commonly seen in constrained virtual environments with clear goals and markers of progress; these diagnostic/formative-feedback strategies are more difficult to implement in open-ended environments with a larger range of potential activities and more variation in problem-solving strategies. This study investigates the potential for using a long short-term memory network (LSTM)-based model to enable stealth assessment in an immersive virtual world for learning. We investigate how well these temporally-sensitive models can predict learning gains on a pre-post survey, as well as predicting the quality of a student-generated concept map. This method is applied to log file data from a middle school science curriculum based on an open-ended immersive virtual environment. Results indicate that the LSTM-based model outperforms support vector machine and random forest models and can accurately predict performance without knowing pre-scores. This deep learning approach is promising for stealth assessment and formative feedback in open-ended virtual environments.

Keywords

Stealth assessment, immersive virtual world, deep learning, recurrent neural network, LSTM.

1. INTRODUCTION

Technology-enhanced learning opportunities through game-based learning and assessment are becoming more common in classrooms, and these novel forms of teaching require a rethinking of how to assess student learning across digital and physical spaces [1]. With an increased research focus on how game-based learning can promote 21st century skills [2], scholars and developers of virtual environments are more frequently considering how difficult-to-measure constructs like problem solving and scientific reasoning can be taught and evaluated. Structured simulations have been used for decades in science to model and explore difficult to perceive or

manipulate phenomena [3,4] but these tools are typically isolated as specific laboratory experiments and are not embedded in authentic frameworks. More complex and less structured environments designed for inquiry learning offer chances for social interaction and participation in the practices of science [5].

Unlike traditional summative assessment of student work, stealth assessment can be employed in virtual settings to diagnostically gauge student competency across a variety of constructs without interrupting immersion and learning [6]. Within the framework of evidence-centered design, virtual tasks are designed to generate logged actions that can act as evidence for a competency model of a certain construct [7]. This type of formative assessment has been applied to a variety of epistemic games as well as games for learning [8] and can provide a foundation for developing feedback mechanisms and dynamic scaffolding to students [9]. This approach to assessment and feedback generation encounters challenges when applied to open-ended virtual environments.

This study presents several ways of using recurrent neural networks trained on student logged actions over time in an open-ended virtual environment for learning in order to predict student learning across several constructs as well as the quality of a student-generated concept map. The effects of temporality in the data and the impact of including pre-survey measures are explored.

2. LITERATURE REVIEW

Well-designed educational games and computer-based simulations engage and excite learners while offering a chance to interact with a dynamic virtual world [10]. Virtual environments have been used effectively in science education to foster inquiry and learning not only of content, but also of the fundamental frameworks and practices of science [13]. Game-driven intelligent tutoring systems and game-based assessments have driven the field to consider the role games and assessments have in case-based teaching [14], how higher-order inquiry skills can be assessed in science [15], and how traditional psychometrical considerations do or do not apply to these new tools [16].

Stealth assessment and educational data mining of virtual worlds have been applied successfully to a variety of science-oriented games and curricula. In-game actions of students correlated significantly with pre-post content assessments [17]. Other work explored how tool use and completion of specific content generates multiple potential pathways students take in successfully completing tasks [9]. Determining implicit understanding of science concepts based on observed strategic moves in game-based assessments is also possible, although it still typically requires significant human coding [19].

Joseph Reilly and Chris Dede "Exploring Stealth Assessment via Deep Learning in an Open-Ended Virtual Environment" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 643 - 646

More researchers are exploring the applications of deep learning techniques to stealth assessment. Min et al. proposed the *DeepStealth* framework, which showed stacked denoising autoencoders could significantly outperform traditional machine learning methods in predicting student gains during a game-based learning curriculum [20]. LSTM-based models seem well-suited to the task of stealth assessment, outperforming comparable models in stealth assessment with no hand-engineering of features [21]. These models can also be combined with unsupervised learning techniques to identify problem-solving behaviors in learners and to predict learning gains [4].

Many of these techniques, however, do not work for more open-ended environments. Akram et al. note that their clustering approach, “is not appropriate for analyzing ill-defined problems where players are not bound to certain actions” [4]. In less strictly-defined learning environments, there is no set series of challenges to tackle or sub-goals to accomplish in service of a defined goal. Instead, users are free to revisit and repeat aspects of the world, do things in whatever order they see fit, and generally proceed in more erratic ways.

3. RESEARCH QUESTIONS

This study attempts to answer the following research questions:

1. Can team learning gains in the EcoXPT curriculum be accurately predicted from their logged trace actions?
2. What impact do the survey features have on the ability to predict learning gains?
3. How important is the temporality of data for the LSTM-based models?
4. Can the quality of teams’ final concept maps be accurately predicted from their logged trace actions?

4. ECOXPT CURRICULUM

4.1 Overview

The EcoXPT virtual world is the foundation of a twelve-day ecosystem science curriculum designed for use in middle school science classes [12]. Students work in small teams (2-3 students with one device) to explore a virtual pond ecosystem and its watershed, talk to non-player characters in the virtual world, collect data about water quality, and conduct authentic experiments. This inquiry-based curriculum teaches ecosystems science, scientific inquiry, and complex causality. There are no specific quests given or sub-tasks assigned, and no one “correct” answer is expected from teams. Many static scaffolds are built into the virtual world, but feedback is not based on the teams’ actions.

4.2 Dataset

The data for this study was collected as part of two larger studies comparing EcoXPT to an earlier immersive world-based curriculum developed by our team. After cleaning, logs from 320 teams of students from 16 different teachers were analyzed. All schools in this sample are urban/suburban public middle schools located in the northeastern United States. Logged records of student actions containing no identifiable information were stored during every session in a PostgreSQL database.

During this study, participating students completed a pre-post survey with six constructs: affective dimensions, ecosystem science content, understanding of causality, correlation versus causality,

experimental methods, and epistemology. As a final deliverable and representation of each team’s conclusive understanding of the complex causal web of interactions that lead to the fish dying, a causal concept map tool is used to show how factors in the ecosystem affect each other. Students drag nodes onto a board and connect the nodes with arrows indicating the direction of causation. Prior work has automatically analyzed student concept maps to evaluate overall structure, inclusion of correct and incorrect claims, and the types of evidence used by claim [11].

5. METHODS

Our main aim is to evaluate how well teams’ in-world actions can predict gains on our surveys as well as the quality of their concept maps. These logged actions contain meaningful temporal relationships, as these series of interactions represent problem-solving and exploratory strategies teams employed during the curriculum. Like other recent work on modeling temporal dependencies in log file data, we use a classifier model based on a LSTM. We also utilized more traditional classifiers that do not account for the temporal relationships in our data: a support vector machine (SVM) and a random forest (RF) model. In order to move beyond pre-post assessment and towards stealth assessment, several different versions of our features were used. One version contained only pre-test information, the second contained only logged actions, and a third feature set contained both. This allowed us to estimate the importance of the temporal dependencies the LSTM-based model leverages and showed how much more predictive power those models afford.

5.1 Data Pre-processing

This paper focuses on gains in three of the six total constructs: ecosystem science content, understanding causality, and experimental methods. Students completed the surveys as individuals, so average team pre- and post-scores were calculated for all teams in the study. As done in [4], survey performance was divided into low, medium, and high performers by setting thresholds at tertile values. This creates roughly balanced classes and allows simple interpretation of all survey constructs. Team concept maps were scored for accuracy according to a rubric designed by an ecosystem science expert [11] that separates claims made by students into core claims essential for understanding the complex causality of the ecosystem, tangentially related claims, and incorrect claims.

To reduce the dimensionality of the data, we binned our 68 events into six coarser-grained meta-categories that encompassed the range of different activity types available in the EcoXPT virtual world [18]: explore, collect, analyze, experiment, hypothesize, and tutorial. After classification, these categories were one-hot encoded. Combined with one-hot encoded tertile assignments for student pre-scores on the survey constructs, this resulted in nine features for use in classification. For the random forest and support vector machine models, cumulative counts of the one-hot encoded meta-categories were calculated. Each team thus had one observation of nine features. The LSTM model uses a three-dimensional tensor with dimensions of [samples, time steps, features].

5.2 Classifiers

We utilized the sci-kit learn package for Python to train random forest and SVM classifiers on our data and Keras for the LSTM-based model. Two-thirds of our teams were randomly selected to

act as a training set, while the remaining third of teams act as the test set. 5-fold cross-validation was used to tune hyperparameters.

As a baseline, the most common label for all classes for each survey or concept map was assigned to all teams. Grid search with 5-fold cross-validation was used to optimize the regularization parameter of the SVM model for each of our feature sets. As with the SVM model, grid search with 5-fold cross-validation was used to optimize the number of trees used.

Due to the lengthy training time of recurrent neural networks, LSTM hyperparameters were chosen initially based on those from similar literature [21, 4] then tuned by hand. Our final LSTM-based model was kept intentionally simple to reduce overfitting on a small sample of team logs. A single bidirectional long short-term memory layer with three neurons was used along with a dropout of 0.75 to both the input and recurrent connections. This layer output to a fully connected layer with a softmax activation that made the class assignments. The model utilized the Adam optimizer with a categorical cross-entropy loss function. The models could train for up to a maximum of 100 epochs.

6. RESULTS

6.1 Predicting Post Scores

The accuracies of our baseline classifier as well as our three classification models for three survey constructs are summarized in Table 1. The highest accuracy for each construct is in bold.

Table 1. Accuracy of classifiers when predicting post-score on three survey constructs.

Classifier	Content	Causality	Methods
Baseline	36.1%	35.1%	38.1%
SVM	63.2%	73.4%	69.4%
RF	61.2%	75.5%	68.4%
LSTM	68.8%	78.6%	73.5%

It is likely that this dataset’s use of pre-determined meta-classifications is more likely to yield higher accuracy for all models as this feature engineering step reduces dimensionality and imparts domain knowledge in the feature set. We attempted to use less-constrained feature sets as inputs for the LSTM-based models but issues of overfitting, training time, and limited memory capacity were limitations for the current analyses.

6.2 Importance of Survey Features

We investigated the effectiveness of using solely our logged user activities by constructing a partial feature set that omitted team pre-survey data. The performance of our LSTM-based model on both feature sets is shown in Table 2.

Table 2. Performance of LSTM-based model when predicting content post-score with and without pre-score information.

Features	Accuracy	Precision	Recall	F1 Score
Only logs	50.5%	0.255	0.505	0.339
Combined	68.8%	0.742	0.687	0.637

The inclusion of the pre-survey performance features improves model accuracy by roughly 17%. This indicates that a large amount of predictive power in the model comes from the logged features.

6.3 Predicting Concept Map Quality

Using the quality of student-generated concept maps as a target variable allows us to use solely data from the virtual world as both target and predictor variables. The performance of our three classifiers is reported in Table 3.

Table 3. Performance of classifiers when predicting concept map quality.

Features	Accuracy	Precision	Recall	F1 Score
SVM	37.9%	0.392	0.379	0.371
RF	43.9%	0.462	0.455	0.442
LSTM	48.5%	0.339	0.485	0.399

6.4 Importance of Temporality

In order to assess the importance of the order of logged actions for making accurate predictions, a new deep learning model was fit that did not have any recurrent layers and where connections do not form a cycle to learn from previous sequences. A feedforward neural network consisting of two fully connected layers with six hidden units each and “relu” activation was trained to accomplish the same concept map quality prediction task described in Section 6.3. This model’s accuracy was able to match that of the random forest (43.9%) but could not match that of the LSTM network.

7. DISCUSSION

The LSTM-based models consistently outperform their the highest performing SVM and RF models as well as the majority class baseline. These performance differences are like those reported in similar deep learning stealth assessment models [21]. While a small amount of feature engineering based on expert content knowledge is done here to reduce dimensionality of the feature set, automated methods of doing so in the future could remove even this barrier to fully automatic stealth assessment of open-world environments. These classifications can act as formative assessments for teachers to direct their attention during implementation of the authentic scientific inquiry curriculum to students who most need help. Additionally, fail-soft interventions could be included in the program itself that trigger based on patterns in the longitudinal record of teams’ actions.

Our small sample size might lead to low accuracy. Our current analysis also ignores the role of the class and teacher that teams are assigned to. Ongoing work in our group on teacher fidelity of implementation shows that teachers vary significantly in the amount and quality of support offered to their classes. Our current concept map scoring metric is a work-in-progress, and we may be able to triangulate our concept map scoring methods with observed learning gains to ensure that our dependent variable is an accurate representation of team understanding of causality.

The techniques presented here are a first step toward applying deep learning stealth assessment techniques to an open-world immersive virtual environment for learning. Future work will take a more fine-grained look at logged events with a focus on exploring how actions within the different experimental tools might afford a better assessment of student understanding of causality. Employing concept coding strategies via unsupervised methods to classify different types of maps may allow for more automation and increased generalizability of this method. Teams enter free response text as reasoning to justify their claims in the concept map and these data have not yet been analyzed. Natural language

processing techniques may lead to a deeper understanding of how teams use causal reasoning when making claims.

8. CONCLUSION

This study successfully applied deep learning techniques from games for learning literature to open-ended environments for learning. Using data collected from several implementations of a multi-week virtual environment-based curriculum, we evaluated several popular classifiers in the educational data mining literature and showed that a LSTM-based model consistently outperformed them. These models can operate unobtrusively while teams make their way through the curriculum. Classifications regarding the capabilities of teams across several different constructs can inform interventions administered directly through the virtual world or flag certain teams for the classroom teacher to follow up with. Future work will involve further optimization and regularizations of the model to improve performance as well as training the assessor on other versions of the logfile data with different grain sizes.

ABSTRACT

Randomized controlled trials (RCTs) can be embedded in educational technologies to evaluate how interventions affect student outcomes and how effectiveness varies with characteristics like prior knowledge. But RCTs often assign many students to ineffective conditions. Adaptive algorithms like contextual multi-armed bandits (MABs) could change how students are assigned to conditions over time, offering the potential to both evaluate effectiveness for subgroups of students and direct more students to interventions that are effective for them. We use simulations to compare contextual MABs to traditional RCTs and non-contextual MABs. Contextual MABs improve outcomes for each subgroup; in contrast, non-contextual MABs may help one group of students, such as those with high prior knowledge, while hurting another. Because both MAB algorithms adaptively assign conditions based on prior students' results, both recover biased estimates of condition effectiveness. However data collected from a contextual MAB is still nearly as good for inferring the optimal assignment policy as from an RCT.

1. INTRODUCTION

Randomized controlled trials (RCTs, sometimes known as A/B testing in software) can identify both how effective an intervention is overall and whether its effectiveness varies systematically based on individual characteristics of students (as in, e.g., [2]). Yet, RCTs may assign many students to ineffective conditions. Adaptive experiments can help by adjusting condition assignments based on their effectiveness for previous students. Multi-armed bandit (MAB) algorithms have been explored as a way of conducting such adaptive experiments in educational technologies [8, 11].

We explore the impact of MAB algorithms when there are participant-treatment interactions with different optimal con-

ditions for subgroups of learners. For instance, students with lower prior knowledge benefit more from concrete versus abstract examples, while the opposite holds for students with higher prior knowledge [2]. *Contextual* MABs have the potential to learn how effective conditions are for individuals [7]. These algorithms estimate condition effectiveness as a function of features, such as prior knowledge. We propose using contextual MABs to conduct personalized experiments that assign students to conditions based on their characteristics and simultaneously estimate how these characteristics impact the (differential) effectiveness of the conditions.

However, collecting data via contextual MABs has the potential to introduce biases: unlike in an RCT, condition assignment is dependent on an individual's characteristics and the assignments and outcomes of previous students. When conducting experiments using non-contextual MAB algorithms, the latter feature can bias the measured effectiveness of conditions, skewing the results of hypothesis tests [5, 9].

In this paper, we explore the tradeoff between *maximizing* how many students receive the most effective version of a technology for their individual learning needs and *estimating* the effectiveness of different versions of a technology. Using simulations, we compare three ways to assign students to experimental conditions, such as the different versions of an educational technology: uniform random assignment as in a typical RCT, a non-contextual MAB as in [11], and a contextual MAB that adaptively personalizes based on student characteristics. We consider scenarios in which a single feature, such as a student's prior knowledge, impacts what condition leads to the best outcome for the student, and examine cases where there is also an overall main effect of condition (i.e., averaged across all students, one condition is better than the other) versus cases where there is only an interaction effect between the student feature and the condition. Specifically, we investigate the following questions:

1. When does a contextual MAB assign more students to the most effective condition for them than the other policies, and how does this vary over the course of the experiment?
2. To what extent is there bias in the estimates of condition means for different subgroups? How does this impact the probability of inferring the optimal policy from the data?

We find that contextual MAB improves student outcomes compared to a typical RCT or non-contextual MAB. Fur-

Hammad Shaikh, Arghavan Modiri, Joseph Jay Williams and Anna Rafferty "Balancing Student Success and Inferring Personalized Effects in Dynamic Experiments" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 647 - 650

thermore the RCT is only slightly better than the contextual MAB in inferring the optimal policy. However both MABs introduce some bias: this manifests in the estimation of the participant-treatment interaction effect for contextual MABs, versus the main effect for non-contextual MABs.

2. CONTEXTUAL MAB ALGORITHMS

MAB algorithms are used in online decision-making scenarios in which a system must repeatedly choose an action in an effort to maximize reward. Initially, the relation between reward and actions is unknown to the system. A *contextual* MAB algorithm is used if an action's reward depends on both the action itself and the features of the data point (i.e., the context). Throughout this paper, we consider the following example of an educational experiment as a contextual MAB problem: students complete a homework activity, and are assigned to one of two experimental conditions: video or text hints. The experimental conditions are *actions*, and the *reward* is the student's score on the next homework activity. The effectiveness of text versus video hints is not known at the outset, and may vary according to the student's prior knowledge: *low* versus *high*. The system learns this relationship over time. More formally, for each student i with prior knowledge X_i , the system assigns a condition a_i and observes the resulting homework score R_i . To assign a condition to student $i + 1$, the system uses the student's prior knowledge X_{i+1} and the outcomes of all previous conditions assigned to students $1, \dots, i$. The optimal *policy* for assigning a student to a condition is the policy that chooses the action a^* with the highest expected reward based on the student's prior knowledge: $a_i^* = \operatorname{argmax}_a E[R_i(a) | X_i]$, where $R_i(a)$ refers to the reward (e.g., homework score) for student i as a function of the chosen action.

Contextual MAB algorithms must balance exploring what actions are effective based on the feature value(s) and exploiting information learned from the past action choices. Most contextual MAB algorithms, including Thompson Sampling [1] which is used in this paper, seek to minimize *cumulative average regret*: mean regret after n students is

$$\frac{1}{n} \sum_{i=1}^n E[R_i(a_i^*) | X_i] - E[R_i(a_i^{\text{actual}}) | X_i],$$

where a_i^{actual} is the actual action chosen for student i . In this paper, we focus on parametric contextual bandits where the expected reward $E[R_i(a) | X_i]$ is modeled as a linear regression function. In our example, assume we formulate the low or high prior knowledge of student i with $X_i = 1$ or $X_i = 0$, respectively. Then, we can use the following regression equation to describe the reward function:

$$E(Y_i | D_i, X_i) = \beta_0 + \beta_1 D_i + \beta_2 D_i X_i, \quad (1)$$

where D_i is 1 if student i is assigned to text hints and 0 for video hints. Note that we assume the contextual feature does not impact the outcome to simplify the exposition of our results. A primary benefit of this linear model is that each parameter represents a quantity of practical interest to researchers. For instance, $\beta_0 = E(Y_i | D_i = 0, X_i = 0)$ is the average achievement for students with high prior knowledge who received a video hint, and β_1 is the effect on achievement for text hints relative to video for students with high prior knowledge. Finally, β_2 is the differential benefit of re-

ceiving text hints for low prior knowledge students relative to students with high prior knowledge.

In this paper, we use Thompson sampling [1], which stochastically selects an action based on its probability of being the optimal action. Thompson sampling periodically estimates the regression equation (equation 1) using regularized Bayesian regression. We assume a conjugate normal-inverse gamma $N\text{-}\Gamma(0, \mathbf{I}, 0, 0)$; the prior corresponds to L_2 regularization (i.e., ridge regression), penalizing large coefficients.

3. RELATED WORK

MAB algorithms have been used in past work to conduct experiments within educational technologies, such as identifying the most effective explanations in an online quiz [11]. Contextual MAB algorithms have also been used in personalized intelligent tutoring systems in which the algorithm selects problems with appropriate difficulty level based on the students' profile [3]. In this paper we add to this literature by exploring the trade-off between assigning a higher proportion of students to their optimal intervention while also learning how the impact of an intervention varies across contextual features of students, similar to the exploration in [9] for non-contextual MABs.

Within the MAB and contextual MAB literature, identifying differences among actions (here, experimental conditions) and reliably measuring the degree of difference is an active area of research. In situations where user features are likely to have high impact on outcomes and there are many actions, randomized experiments can be impractical due to a combinatorial explosion of possibilities [6]. That work shows contextual MABs can be effective in high dimensions, motivating some of the current work. Several MAB algorithms have been proposed that change the loss function to increase measurement accuracy [5] or increase the chance of correctly identifying causal effects [10], and other work has developed MAB variants that correct for biases in estimated effects by re-weighting the data [4]. Our research builds on this prior work by detailing the extent of the measurement bias in a standard contextual MAB algorithm and investigating bias due to use of a non-contextual MAB when participant-treatment interactions are present, such as a student's prior knowledge influencing condition effectiveness.

4. INVESTIGATING MAB IMPACT

In simulations, we investigate the effectiveness of adaptive experiments using a MAB versus a standard RCT both in terms of average student outcomes and for evaluating the relative effectiveness of different conditions. When designing an adaptive experiment, the researcher must decide whether participant-treatment interactions should be included by deciding whether to use a contextual or non-contextual MAB algorithm. We explore the consequences of incorrectly using a non-contextual MAB in a situation where condition effectiveness is dependent on student's prior knowledge. We predict that contextual MABs will be most effective at assigning students to the best condition for them, and even when the non-contextual MAB recognizes that one condition is on average more effective than another, the contextual MAB will learn this more quickly. However, it's likely that both types of MAB algorithms may overestimate effect sizes, consistent with biases in experiments without contextual effects [9].

4.1 Simulation Framework

All simulations assume a sample of 1000 students. This is the size of a very large university classroom or the number of active users in an average MOOC; we also report on results after 250 students, corresponding to a somewhat smaller university class. We assume a binary condition $D_i = I(i \text{ in treatment group})$ and a single binary contextual variable X_i . The binary contextual variable of our study follows a Bernoulli distribution with $P(X_i = 1) = 0.5$. Such binary variables are common in educational contexts, such as when representing a student's prior knowledge as below or above the median student. Outcomes (reward) are generated using a linear regression model that estimates the reward of providing two groups of students (low versus high prior knowledge, differentiated by $X_i = 1$ versus $X_i = 0$) with a video or text hint ($D_i = 0$ or $D_i = 1$):

$$Y_i = \beta_0 + \beta_1 D_i + \beta_2 D_i \times X_i + \epsilon_i,$$

where $\beta = (\beta_0, \beta_1, \beta_2)$ are the parameters of interest and $\epsilon_i \sim N(0, 1)$. We set $V(\epsilon) = 1$ so that the regression coefficients approximate Cohen's d effect sizes. We consider the case with cross-over interaction where the optimal condition for each contextual group is different from the other one. In this settings, two distinct scenarios are covered; 1) **Context-only**: No main effect averaged across groups for text versus video hints, but the main effect within each contextual group is prominent (outcome generating model: $Y_i = 0 + 0.3D_i - 0.6D_iX_i + \epsilon_i$). 2) **Main-plus-context**: There is an average main effect in addition to the main effect for each group (outcome generating model: $Y_i = 0 + 0.3D_i - 1.2D_iX_i + \epsilon_i$).

For each scenario, we compare three policies: uniform random sampling, non-contextual and contextual multi-arm bandits. Non-contextual MAB does not contain a term that includes X , while contextual MAB includes this term (eq. 1). All results average 2500 repetitions of each simulation.

After the data are generated using one of the three assignment methods (e.g. uniform, non-contextual MAB, or contextual MAB), we fit an ordinary least squares (OLS) regression with terms for both effect of D and the interaction between D and X (the true outcome generating process shown in equation 1). Then for each treatment assignment policy and outcome generating scenario, we evaluate the i) Regret of action (difference in rewards between the optimal action and the assigned action), ii) Proportion of students assigned to the optimal condition for them, iii) Bias of coefficients of the fitted model (mean of estimated coefficients across simulations minus the corresponding true value), and iv) Proportion of simulations in which the OLS fitted model implies the true optimal policy.

4.2 Simulation Results

Context-only: No Main Effect. When there is no main effect, only the contextual MAB improves student outcomes. After only 250 students, the contextual MAB assigns an average of 77% of students to their optimal condition (Table 1). Because the non-contextual MAB cannot differentiate between individual students, both the non-contextual MAB and uniform random policy assign about 50% of students to their optimal condition.

Figure 1: The cumulative regret at each iteration (left). The biases of the coefficients of the OLS model fitted on the generated data up to the specified user iteration (right). Outcome are generated by the model $Y_i = 0 + 0.3D_i - 1.2D_iX_i + \epsilon_i$ and averaged across 2500 repetitions.

The contextual MAB's adaptive assignments leads to systematic differences between the estimated model and the true data-generating model: the relative effectiveness of receiving text hints ($D = 1$) for students with high prior knowledge ($X = 0$) compared to lower prior knowledge ($X = 1$) is incorrectly estimated. After 1000 students, the estimate of β_2 is roughly 19% lower than its true value. Random variation in outcomes combined with the algorithm's adaptivity cause this overestimation of the effect size ($\beta_2 < 0$ and $\text{Bias}(\hat{\beta}_2) < 0$): the algorithm is more likely to stop assigning students with low prior knowledge to text hints when its benefit is below, rather than above, its expected value. Although bias is present, the resulting fitted model implies the correct optimal policy in 99% of repetitions.

Both the non-contextual MAB and the uniform random policy assign half of students to each condition, independent of prior knowledge, so both recover estimates of the effects that are quite close to the truth. However, the non-contextual MAB has more variance than the uniform random policy in its condition assignments, resulting in noisier estimated effects as reflected in the standard errors.

Main-plus-context: Main effect and larger effect for one subgroup. When there is both a main effect overall and a differential effect based on a student's prior knowledge, all three assignment methods differ in the degree to which they direct students to a more effective condition and in the biases in their estimates of the effects. As shown by lowered regret in Figure 1 (left), both MAB algorithms achieve better average student outcomes over the uniform random policy. Contextual MAB assigns students to conditions that are beneficial for them based on the feature value. However, non-contextual MAB cannot differentiate its policy based on students' prior knowledge. Since the overall main effect is negative (video hints are better than text hints on average), the non-contextual MAB learns to assign more students to videos over time. In smaller samples (left of Table 1), 82% of students with low prior knowledge are assigned to their best condition whereas only 18% of students with high prior knowledge are assigned to text hints although it is most beneficial for them. Thus, if heterogeneous effects are present, experimentation using a non-contextual MAB policy can be systematically worse for some students than the uniform random policy.

As in the **context-only** scenario, the contextual MAB overestimates the value of text hints for students with lower prior

knowledge ($\beta_1 + \beta_2 < 0$ and $\text{Bias}(\hat{\beta}_1 + \hat{\beta}_2) < 0$ in Table 1). The non-contextual MAB instead underestimates the effectiveness of text hints relative to video hints for students with high prior knowledge ($\beta_1 > 0$ and $\text{Bias}(\hat{\beta}_1) < 0$). Both patterns of bias occur because of the combination of random variation in outcomes combined with adaptive sampling, and the difference stems from whether the adaptive sampling is sensitive to contextual features. Prior work shows that less effective conditions tend to be underestimated by MABs, which usually leads to *overestimation* of effect sizes [5, 9]. Our results demonstrate that when heterogeneous effects are present but a non-contextual MAB policy is used, underestimation of the value of a condition that is worse on average can lead to *either* underestimation or overestimation of effect sizes for subgroups of students. When a condition is worse on average but better for some students, such as our text hints for students with high prior knowledge, the size of the effect for those students will be underestimated ($\beta_1 > 0$ and $\text{Bias}(\hat{\beta}_1) < 0$). The size of the effect of condition for the other students, such as our low prior knowledge students, will then tend to be overestimated ($\beta_1 + \beta_2 < 0$ and $\text{Bias}(\hat{\beta}_1 + \hat{\beta}_2) < 0$).

5. CONCLUSION

In this paper we focus on a scenario in which the impact of a binary condition assignment (text versus video hints) on a continuous student outcome depends on a binary contextual feature (low versus high prior knowledge). We find that assigning students to conditions using a contextual MAB significantly reduces regret relative to traditional RCTs and non-contextual MAB. Although adaptive, personalized experimentation can help more students benefit from experimental interventions and does accurately recover the direction of effects, the estimated differences of personalized effects across student subgroups will be biased. However for contextual MAB the presence of bias does not significantly impact the probability of inferring the optimal policy relative to a traditional RCT. Future directions include evaluating the effectiveness of methods to correct for the biases documented here, and using contextual MABs in real educational technologies to conduct adaptive experiments in settings where personalized treatment effects are expected.

ABSTRACT

The research area of analyzing log file trace data to build academic performance prediction models has tremendous potential for pedagogical support. Currently, these learner models are developed from logs that are composed of one intermixed stream of data, treated in the same manner regardless of which platform (mobile, desktops) the data came from. In this paper, we designed a correlational study using log data from two offerings of a blended course to investigate the effects of the variables, derived from the use of varying platforms, on the prediction of students' academic success. Given that learners use a combination of devices when engaging in learning activities, it is apparent that weighing the logs based on the platform they originate from might generate different (possibly better) models, with varying priority assigned to different model features. For instance, our results show that the overall frequency of course material access is a less powerful indicator of academic performance compared to the frequency of course material access 'from mobile devices', probably due to the benefits associated with ubiquitous any-time access available to mobile learners. Thus, the primary goal of this study is to bring to light the potential for improvement of prediction power of models after considering the learner's platform of access, within the learning analytics community and the fields of user modeling and recommender systems, in general.

Keywords

Learner Models, Learning Success, Learning Analytics, Mobile Learning

1. INTRODUCTION

The performance prediction models use students' logs from various learning activities that are available for measurement such as logging in, reading files, viewing posts, posting discussions and accessing feedback. However, research has

provided evidence suggesting not all activities (features) are equally effective as predictors of outcomes [3]. Moreover, research has also suggested that not all the learning activities are performed using a single technological modality [4, 6] but are often interleaved between devices such as mobile and desktop. In other words, depending on the utility and preference for a modality, the predictive power of learning indices (variables describing the frequency and/or quality of interaction with the LMS tool) in a regression model could be positively or negatively impacted. Building upon these inferences, we further posit that acknowledging the differences in the source of the log trace data used for modeling and predicting academic success, would promote increased accuracy of prediction models and explain anomalies. This hypothesis is supported by the results from a recent study [5] where the authors found a significant impact of the students' adopted platforms (and patterns of usage) for various learning activities on the final course grade.

The review of the literature reveals that the performance prediction models draw benefits from the students' 'event-driven logs' [1] from various learning activities that are available for measurement in a web-based learning management systems (LMSs) such as logging in, reading files, viewing posts, posting discussions and accessing feedback; all of which provide early indicators of student academic performance [8, 9, 2]. These logs, however, are composed of one intermixed stream of data, treated in the same manner regardless of which modality (mobile, desktops) the data came from. As a rule of thumb, the data concerning each predictor action, such as posting discussions and viewing course videos – actions that more often than not, emanate from different modalities and last for different durations – is generally pooled across all modalities. For instance, the frequency of access to course material from desktops, mobiles and tablets is typically used in the predictive model as one cumulative count measure i.e. *course_material_access*, counting all occurrences of course material access in the log file. This is done mainly due to the lack of awareness regarding the utility of technological context or merely to facilitate ease of data processing. Either way, the omission of technological modality variables in a model has potential to, at minimum, discard some useful information and as a result lower the prediction accuracy of the model, or more critically, cause serious threat to its interpretation. Thus, the primary aim of this paper is to create awareness of the role of modalities

Varshita Sher, Marek Hatala and Dragan Gasevic "Investigating effects of considering mobile and desktop learning data on predictive power of learning management system (LMS) features on student success" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 651 - 654

in predictive analyses of academic performance.

The exploration of the impact of modalities on predictive analytics is justified and highly recommended since: (a) learning activities are often completed by students using multiple modalities, used either sequentially or simultaneously [4, 7], and (b) identification of modalities that are ill-aligned to a task is important as they could undermine knowledge construction and may lead to unintended consequences in academic outcomes [5]. This paper thus investigates the usefulness of a modality-inclusive learner model, over and above a generalized model, for predicting learner success (operationalized by academic performance).

2. METHODOLOGY

2.1 Study Design

The study follows a correlational design as it investigates the effects of the variables derived from the trace data from different modalities, on the prediction of student's academic success, operationalized via percent mark - a continuous variable ranging from 0% to 100%. The data was collected over two semesters (Fall 2017 and Fall 2018) from two subsequent offerings of the same course. The course lasted 13 weeks and had a combined enrolment of 165 students (83+82). The course used blended delivery, utilizing the university's learning management system (LMS) to support learning activities and students' overall schoolwork. In addition to the web-browser versions of the LMS (desktop/laptop/ mobile), students had access to the mobile app version provided by the LMS vendor. Upon comparison of the features and functionalities offered by the two versions, no apparent differences were revealed. In the next section, we describe the various kinds of variables that were derived from log files.

2.2 Feature Engineering from LMS trace data

To investigate the effect of modality on different types of commonly included learning-related activities and their traces in the online courses, we selected 10 features (5 counts + 5 time spents for each activity) for inclusion in our analyses as predictors of academic success. Variables derived from the LMS trace data include information about the usage of the following tools/features: syllabus, course material (lecture + tutorial slides and instructor provided supplementary material), assignments, feedback on the assignments and calendar. Table 1 contains the types and total counts of learning actions, categorized into activities, captured by the LMS.

Table 1: Breakdown of activities and access (in terms of the number of actions) from different modalities.

Activity	Desktop	Mobile	Tablet
Assignments	15,929	2,474	23
Calendar	1,734	4,687	43
Course Material	24,850	1,279	147
Submission Feedback	1,954	2,968	6
Syllabus	1,952	155	8

Next, for each student we extracted the number of times and the time spent on using a particular feature by aggregating individual operations such as adding student's assignment views across all four assignment tasks to compute *count_assignment*. We call these variables *LMS features*. Each of these variables was split up further to account for the platform used to access that particular feature. For instance, in addition to having total number of assignment views for a student, we compute three more variables - mobile views, desktop views and tablet views- which indicate the respective number of course logins from each of the three main modalities. We call such variables *Modality features*.

The trace data for both LMS and modality features were initially collected as continuous variables. However, tablets were not used by many students, and therefore variables accessed from tablets were dichotomized into the *Accessed* and *Did not access* categories. Additionally, highly skewed variables were transformed using Box-cox transformations to correct their skewness. If the skewness still persisted, they were transformed into categorical variables and the cut-offs were decided arbitrarily to best represent the data.

2.3 Statistical Analyses

For each of the ten learning features introduced in Section 2.2, two regression models (Figure 1) were built using (a) LMS action variable, i.e. LMS feature (Model 1: simple linear regression), and (b) LMS action variable with information on modality source, i.e. Modality features (Model 2: multiple linear regression), to assess the importance of the platform source of the log data for predicting student percent marks. For each of the ten features, a change in R^2 from Model 1 to Model 2 is calculated to present the percentage of variability in student percent mark explained by Modality features over and above the LMS features. To ascertain whether the change was statistically significant, an ANOVA analysis using F-test of the statistical significance of the increase in R^2 was conducted.

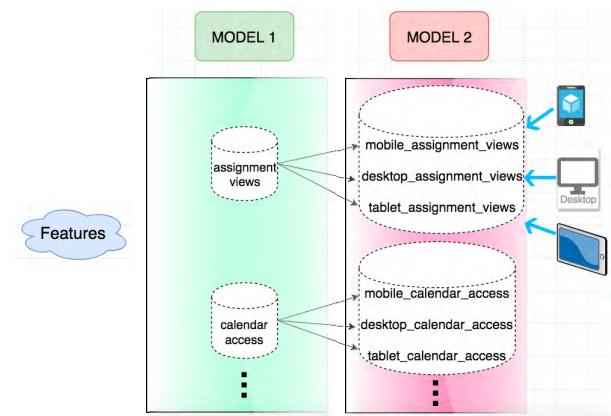

Figure 1: Feature selection for the two models.

3. RESULTS AND DISCUSSION

The results of the regression models featuring the associations between students' use of features from logged data - calculated cumulatively vs. partitioned based on the modality - and student course grades are presented in Table 2, along with the subsequent model comparisons using ANOVA analyses (columns 5-6 in Table 2).

Table 2: The association between the variables of students’ use of the LMS and Modality features and ln (log natural) student course grades: results of multiple linear regression models.

Activity (a)	Measure (m)	Model 1 $R^2 \times 100$ (p value)	Model 2 $R^2 \times 100$ (p value)	F-value	p-value	Modality features	β Coefficients
Syllabus	count	1.4% (p = 0.12)	3.9% (p = 0.03)	3.16	0.041	Desktop_Accessed 6-15 times vs. up to 5 times	12.36

						Desktop_Accessed 1-10 times vs. Did not Access	-8.11
						Desktop_Accessed more than 10 times vs. Did not Access	1.63

Based on our results of the multiple regression models, we can confirm that the choice of modality for a particular activity in a learning environment plays an important role in the overall model fit and subsequent modal interpretation. The significant ANOVA results imply that an increased proportion of variability in student course grades can be explained if the activity measures are calculated across modalities (Model 2) instead of using one cumulative measure (Model 1).

Interestingly, there was a notable difference in the impact (positive or negative) on the students’ course grades explained by the type of modality – desktop vs. mobile – used to perform the activity. For example, the results of the multiple linear regression analyses performed on the time spent on syllabus access indicated that the mobile access was a significant predictor of student learning outcome whereby course grades of students who used mobile phones for substantive duration (1-2 hours) to access the syllabus were about 13% *lower* than those of their counterparts who did not spend any time accessing the syllabus from the mobile phone modality ($\beta = -12.9$, $p = 0.04$). On the contrary, looking at the time spent on viewing the course assignments, the mobile phone modality reflected a positive association with course grades and explained a greater amount of vari-

ance, such that the course grades of students who used mobile phones to view the assignments for 1-2 hours were about 60% *higher* than those of their counterparts who did not use the mobile phone modality at all ($\beta = 60.3$, $p = 0.01$).

More importantly, the impact of these modalities in explaining the overall fit was not consistent across activities in the learning environment, both in their presence and magnitude. That is to say, *some modalities may or may not play a role in determining student’s course grade depending upon the activity performed using the modality*. For instance, the duration of time spent on a desktop for viewing the assignments was a significant predictor of student course grades whereby a 10% increase in time spent resulted in around 7% increase in student course grades. On the contrary, the same modality was not significant at all when the activity involved engaging with the course material. However, the desktop modality was again found significant for the submission feedback activity where this effect was seven times larger compared to assignment viewing i.e. a 10% increase in time spent on engaging with the feedbacks on assignment submissions resulted in around 47% increase in student course grades.

4. LIMITATIONS FUTURE WORK

Since the feature space in our study is high-dimensional and could easily include interactions and non-linear effects, our immediate next steps involve comparison of machine learning classification methods to test the same hypotheses thoroughly. To further broaden the discussion, there are in fact many features that can be computed from trace data and that are used in the prediction models. As we saw improvements in the ‘crude’ features that we investigated, it is conceivable that we can see improvement in other derived features and therefore improve fidelity of the models.

Furthermore, it would also be interesting to devise, using a bigger participant pool and diverse activity pool, the most optimal learner model comprising a combination of highly explanatory LMS and Modality features from various learning activities as predictors. This, in turn, would require knowledge of several activities in a learning environment for which, modality features can explain more variance in learning outcomes compared to standard cumulative LMS features.

Our methodology involved tracking user interaction with the LMS and this may raise a concern about the extent to which our results were dependent upon the activities targeted in the LMS and the design of the LMS (both browser and app) itself. The types of activities included in our study are quite common in instructional design and usually captured in the same way, thereby rendering good generic results. However, there might be variances in how learning activities are structured and presented in LMS and some LMS can offer even more fine grained tracking to see the influence of modality features from various other activities on the learning outcomes.

5. CONCLUSIONS

Taking up the research on use of mobile and desktop devices in learning environments and its ramifications on learning outcomes one step further, in this paper we looked at how modalities used by students for carrying out learning-related activities in the LMS, could act as powerful indicators of academic success. We designed separate prediction models using measures (e.g., counts and time spent) of activities in the learning environment aggregated across (a) all log data and (b) each individual modality in the log data. We observed that acknowledging a learner’s modality context – i.e. a dynamic entity constructed by the learner through interaction with the learning management system from desktop and mobile devices – led to improvements in the accuracy of models.

To further illustrate the significance of these improvements in predictive power, statistical analyses confirmed the improvements to be significant for most of the predictor measures assessed in this study. While the magnitude of improvements may not be of particular interest, the major take away from the study is that interpretations and subsequent interventions based off of generalized learner models may be improved by utilizing modality-inclusive models, since modalities contribute differently to the learning process depending on the activity they are used for. Further, the significance of this research lies in the simplicity of the method by which the modality of access for a learning ac-

tion/activity can be readily available through capturing the ‘user-agent’ from the students’ log data and the potential high impact it has on the prediction process.

The major highlights from the paper include:

1. Tracing the modality source of log data improves accuracy of learner models
2. Some modalities are better predictors of learning outcomes than others
3. Magnitude of outcome variance explained by modality differs based on the activity
4. Direction of outcome variance explained by modality differs based on the activity

ABSTRACT

This study investigates how we can understand students' actual status in C programming exercises from their learning activity logs. In a face-to-face course of C programming exercise, it is hard for a teacher to see who are in trouble from their appearance. It is not always true that typing something means he or she is making some progress. Therefore it is important to identify, or possibly even predict, students having difficulty from their activity patterns. Most of the prior work paid attention to only trial-and-error activities, such as compile results and execution errors. However, it tends to be overlooked that knowledge acquisition process is also worthy of attention. When a student encounters a compile error, they usually read textbooks to seek a solution. It is considered to be useful for the task whether he or she has an ability to find appropriate pages for error resolution. In this paper, we propose a method to predict whether a student can resolve errors or not. Based on students' activity logs collected from our programming environment and e-book system, we conduct experiments to show and discuss the prediction performance.

1. INTRODUCTION

The C programming language has many obstacles, such as relatively complex syntax and confusing messages of compile errors. In C programming courses, students are required to overcome those hurdles as well as to learn how to solve problems computationally. Especially, because error messages are not necessarily straightforward, students are sometimes led to irrelevant pages of textbooks and get confused. Such learning experiences perhaps lower their motivation to learn, and therefore teachers need to intervene to help students in such situations. However, not all students ask their teachers or friends when they have a tough issue, and it is hard for teachers to distinguish students in trouble from ones without problems by physical appearance. Hence data-driven

approaches have been considered for identifying such *at-risk* students.

Blikstein [1] and Helminen et al. [4] performed a kind of offline analysis of students' behaviors. On the other hand, a realtime-oriented analysis was performed by Fu et al. [3]. They proposed a dashboard system for teachers to grasp the current status of all students in real-time fashion. However, none of them considered the knowledge acquisition process. Helminen et al. [4] addressed the process where students struggle to resolve errors. However, in their study, only limited activities, e.g. selecting, ordering, and indenting code fragments, are analyzed, and activities such as referring external learning materials are not considered.

For understanding students' learning processes, it is significant to know how students search learning resources for necessary information and acquire knowledges. We believe students have to learn how to resolve errors by themselves, and intervention by teachers should be controlled. Hence we have to care how much effort was made by a student to obtain necessary knowledges for resolving errors. Although we could quantize such efforts to some extent by observing how they use their textbooks during programming exercises, only a limited number of studies focused on students' trial-and-error and knowledge acquisition in learning processes of programming languages.

Toward automatic and real-time detection of students in need of help, in this paper, we analyze *error resolution processes* in which students struggle to resolve compilation errors with course materials in a programming exercise course. Furthermore, we try to predict whether they can successfully resolve errors or not in early stage of error resolution processes. Toward this end, we employ both compilation logs and page view logs of e-textbooks, and characterize compilation errors in relation to exercise questions and individual students.

2. METHODS

2.1 Error Resolution Processes

The C Programming Language belongs to the compiled languages, which need a compile process ahead of executing a program. In the compile process, a compiler program transform input source code into a machine code. The process involves a lot of checks and many problems are found as *er-*

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 655 - 658

Figure 1: An example of a timeline. A timeline may consist of three types of events: failure compile event, success compile event, and e-book page reading event.

Figure 2: An example of an error resolution process found in a timeline. Every ERP starts with a failure compile event, but does not necessarily end with a success compile event.

rors before running a program. Errors found in this step could be typically divided into syntax errors and linker errors. The former type of errors requires a student to modify their source code so that it follows the syntax of C language. In the latter case, it usually occurs because of missing libraries and one need to specify required libraries on the command line (or a compiler's configurations). In this study, we call such a process as an *error resolution process (ERP)*, and analyze how students resolve such errors by themselves during exercises.

A sequence of a student's activities is called a *timeline*. A timeline consists of events, and we consider three kinds of events in this study: *failure compile event*, *success compile event*, and *e-book reading event*. The first two types occur when a student compiles his or her source code. If a compile finishes without printing any messages on a screen, we consider it is a success compile event. On the other hand, it is considered as a failure compile event if a compiler outputs some messages. An e-book reading event indicates a student started to read a page of an e-book.

These concepts are illustrated in Figure 1. The figure shows a sequence of eight events from left to right. Every compile events are associated with a problem that a student try to solve. Identifiers of problems are shown at the top right of each event. For this example, one of the possible interpretations of the timeline is as follows; a student were working on the problem 1 and compiled their program for it; however, they got an error from the compiler, and then they rewrite a program according to textbooks and tried again; unfortunately, it did not work well, and he or she abandoned the problem and began the problem 2; they compiled another program, and it successfully finished.

We more precisely describe an ERP based on a timeline. An ERP is a contiguous subsequence of a timeline; an ERP always starts with a failure compile event, and it can include only compile events associated with the same exercise problem. For example, Figure 2 shows two ERPs within a timeline. Since the timeline does not involve another problem in

Figure 3: Possible cases of ERPs whose result could be either *resolved* or *abandoned*.

this case, we can simply identify ERPs as longest contiguous subsequences starting with a failure compile event and containing at most a single success compile event at the end of the subsequence. Another example is shown in Figure 1 which consists of all except the last event.

While several scenario could be considered for ERPs, we simply consider two kinds of outcome from an ERP: *resolved* and *abandoned*. Figure 3 shows examples for both cases. A resolved ERP ends with a success compile event associated with the same problem as the ERP's initiating failure compile event. An abandoned ERP could finish with either an e-book event or a failure compile event. The latter type of ERPs appears when a student switch a current exercise problem to another or a class is over.

2.2 Predicting Outcomes from ERPs

It might be an important information for teachers whether a student's ERP will end up with *resolved* or *abandoned* state. We consider the prediction of the outcome from an ERP in early stage of the process. To characterize EPRs, we employ n-gram features. Firstly, we obtain a textual representation of an ERP. In the representation, every event is notated as a single letter. In this paper, we use *s* for a success compile event, *f* for a failure compile event, *c* for an event of reading e-textbooks especially for the programming course, *o* for an reading event but for other course materials. Furthermore, we also encode gaps between events with - which denotes a gap of just 10 seconds. Any gaps less than 10 seconds are ignored. For example, a gap of 24 seconds is notated as --.

N-gram features are then extracted from the text representation of a timeline. As there are five letters in the representation, an n-gram feature vector will be a 5^n -dimensional vector. For example, if we use 3-gram-based features, a student is represented as a 125-dimensional vector. In this study, we combine 1- to 4-gram feature vectors into a single feature vector, i.e. $5^1 + 5^2 + 5^3 + 5^4 = 780$ -dimensional vector, and use it for making prediction.

Students' first actions are considered important; for example, an expert will read error messages carefully, fix problems, and then recompile the program while a beginner will just repeat the compile or read many pages of textbooks seeking for a solution. We expect such differences are captured by n-gram representations of the first t minutes.

In our experiments, we targeted only ERPs longer than

Figure 4: The distribution of durations of error resolution processes.

Table 1: Hyperparameters adjusted.

Hyperparameter	Candidates
criterion	gini, entropy
max depth	1, 2, 3, 4, 5, 6, 7, 8
max features	sqrt, log2, None

$2t$ minutes. If we use the first t minutes for predicting the outcomes of ERPs whose durations are less than $2t$ minutes, it means that we use more than a half of information to predict the final status of ERPs. That is why we exclude ERPs shorter than $2t$ minutes in this study.

We set $t = 5$ in our experiments. There are 29,216 ERPs in our dataset. Figure 4 shows the distribution of the durations ERPs took. The number of ERPs which only took less than or equal to 10 minutes was 25,886 (88.6%), and the number of our target ERPs was 3,330 (11.4%).

For the prediction, we employ random forest classifiers as a classifier. Random forests are one of the ensemble learning algorithm based on bagging technique and random selection of features [2]. This is one of the most popular classifiers not only in educational datamining community but also in wider data science community. It is known that the classifier is robust even when each dimension of feature vectors has different scales. Therefore, we simply apply random forests to n -gram feature vectors without normalizing them.

We use the implementation of random forest classifier included in scikit-learn package [6] in this study. Basically, we use the default values of the library for the classifier’s hyperparameters except for ones shown in Table 1 and the number of estimators which was set to 100. We optimize these parameters by a grid search algorithm, whose implementation is also provided by scikit-learn. The candidate values for these parameters are shown in the table.

2.3 Data Collection

The course we target is the introductory courses for C programming language in our university. Primarily, all freshmen students takes the course. The class is composed of lectures and coding exercises. There are about 20 classes for the course for each year, and almost all of the courses are taught by different teachers. Although it is not enforced, we

Figure 5: The ROC curve obtained from 5-fold cross validation.

have a set of standard course materials, and they are used in almost all classes.

In exercise, we use the compiler program “gcc”, from the GNU compiler collection. The compiler program is modified from the original version so that it can record students’ learning logs. More precisely, when it is executed, it saves given commandline arguments, the contents of given source files, and the output of the compiler as well as the time and student IDs. Since a commandline and source code are available as logs, we can reproduce what a student tried and what he or she obtained as a result. From those learning logs, we reconstruct compile events in timelines.

We also utilize students’ learning logs on our own web-based e-book system BookRoll [5]. All the course materials are available on the system, and therefore we can collect students’ learning logs about how student utilized those textbooks during exercises. Students’ actions, such as flipping pages and adding highlights, on the system are collected immediately as events occur. In this study, we only focus on page-flipping events collected for our analysis.

3. RESULTS & DISCUSSION

We evaluated our prediction performance using AUC metric, which stands for area under the ROC curve, combining with 5-fold cross validation. The hyperparameter values obtained by the grid search algorithm were `criterion=gini`, `max_depth=6`, `max_features=sqrt`, `n_estimators=10`. Figure 5 shows the five ROC curves obtained during cross validation and the mean ROC curve computed from them.

Table 2 shows the average performance scores with four evaluation metrics. According to the table, we cannot say the performance is good. Although the recall value is relatively high, precision value (especially in the test phase) is low. AUC value for the test phase is better than the chance rate, it is not good enough for practical use.

Table 2: Cross validation result. Values are averaged over five folds.

Metric	Value
AUC (test)	0.566
F1 (test)	0.698
Precision (test)	0.598
Recall (test)	0.844
AUC (train)	0.684
F1 (train)	0.740
Precision (train)	0.640
Recall (train)	0.882

4. CONCLUSION

Focusing on students' error resolution processes, we proposed a prediction method for outcomes from those process. We encode event sequences into texts, and characterize them using n-gram features. From our preliminary analysis, the proposed method could not show a good performance while it has a little bit better performance than the chance rate.

Future work include improvement of the feature representation of timelines and further analysis on the characteristics of student's activities and abilities.

ABSTRACT

Vygotsky's notions of Zone of Proximal Development and Dynamic Assessment emphasize the importance of personalized learning. In this work, we introduce a novel adaptive learning engine named E-gostky that builds on these concepts. E-gostky creates a machine-learning-based skipping policy that presents students with questions which will challenge, but not overwhelm them, keeping students in their Zone of Proximal Development. We evaluated our engine in a real classroom environment, including hundreds of students from several elementary schools. Our results show that using E-gostky can significantly reduce the time required to reach comparable performance. Specifically, in our experiment, it took students who were using the adaptive learning engine 17% less time to reach a similar level of mastery as of those who didn't. Moreover, students made greater efforts to find the correct answer rather than guessing, and class teachers reported that students showed higher engagement.

Keywords

Personalized learning path, e-learning, Adaptive learning, Zone of Proximal Development

1. INTRODUCTION

In the early 1930s, Lev Vygotsky conceptualized the idea of *Zone of Proximal Development* (ZPD), and laid the foundations for the concept of personalized learning [14, 4]. ZPD is defined as "the distance between the actual developmental level as determined by independent problem solving and the level of potential development as determined through problem-solving under adult guidance, or in collaboration with more capable peers" [14, pg. 86]. In other words, it refers to what a learner can do with assistance, but cannot

do independently. According to Vygotsky, concrete growth can only occur in the ZPD, and the learning is most effective when the support is matched to the needs of the learner. However, creating a personalized learning environment is challenging in traditional classrooms, where the teacher is outnumbered by the students. Using modern technology in classrooms supports the teacher in ways that can allow effective personalized learning [5].

Many e-learning systems contain a large set of exercises¹ such that the students moves in a linear order between exercises. However, content served in a non-adaptive manner will under-challenge some students, and over-challenge others. In view of Vygotsky's theory, it can be said that the problem stems from the fact that each student has a different ZPD at a given point in time. The method proposed here tries to mitigate this problem using a quantitative interpretation of the ZPD concept, translating it to a data driven algorithm which supports the delivery of personalized learning content. The method utilizes an adaptive learning engine, named E-gostky, that can move forwards or backwards through linearly structured content to find the next exercise which will be at the right level of difficulty, keeping the student within her ZPD.

To identify whether a task will keep a student within her ZPD, we use another core concept of Vygotsky's theory: Dynamic Assessment (DA). The goal of DA is to assess the potential for learning, rather than a static level of achievement, by prompting students to use their minds and assistance in problem solving. By dynamically evaluating students' progress, we adapt the served content according to the learning potential of the student at the current time and on the current topic.

To test our method, we used content that was developed by pedagogical experts at the The Center for Educational Technology (CET) in Tel-Aviv, Israel, to serve elementary school students while learning fractions. When comparing the students who learned the content in its original form to students who learned using E-gostky, we found that students in both groups achieved comparable performance, yet to reach this

¹The terms "exercise" includes also other activities such as watching instructional videos.

level of mastery, students on the adaptive track required significantly less time ($\sim 17\%$ less time on average)- time which can be used for other educational activities. Furthermore, the qualitative feedback provided by teachers suggests that students using E-gostky were more engaged and eager to learn. One of the teachers reported that “using the skipping engine (E-gostky) ... motivated them to learn, think longer before answering, and use the aids to answer correctly”.

In this document we present the summary of the results. A more comprehensive description of the study and the results can be found at [13].

2. BACKGROUND AND RELATED WORK

The Zone of Proximal Development (ZPD) plays a key role in the method we propose. The ZPD was introduced by Vygotsky with the goal of identifying the psychological functions (and related social interactions) that are needed for transitioning to the next age period, and to assess the current status of a child’s maturing functions [4]. The ZPD provides a framework to evaluate learners’ abilities, known as Dynamic Assessment (DA) [4, 8] which focuses on measuring the learning potential for future development [8]. A dynamic test is based on teacher assistance, where guidance, feedback and adaptive delivery of assistance are embedded in the evaluation procedure itself [4]. While originating from a developmental theory, many benefits of implementing the ZPD and DA concepts in educational applications have been demonstrated, such as increased motivation and higher performance [12, 15].

Our work also relates to past research on using historical data to sequence content for students, a problem that attracted many researchers [6, 11]. For a more comprehensive literature review see [13].

3. METHODS

The adaptive learning method we propose consists of two components: (i) *Dynamic Assessment* - this component predicts students’ performance in proposed exercises (ii) *Sequencing Policy* - this component is a policy in which given the predictions made by the Dynamic Assessment, assigns the next exercise by deciding which exercises are in the current ZPD of the student.

The Dynamic Assessment component is built on features learned by Random-Forests models [3] such as student history, offline exercise metadata and online student-exercises features. These features are then used to predict for each student-exercise pair, two factors: (1) *Time To Success (TTS)* - how much time will the student spend until she finds the correct solution to the exercise, and (2) *Correct at First Attempt (CFA)* - the probability that the student will solve the exercise correctly in her first trial [9, 10]. These predictions are then used to define a policy that is designed to keep students in their Zone of Proximal Development by ruling whether an exercise should be skipped. The skipping policy considers an exercise too easy for a student if she can solve it correctly and relatively fast (see Figure 1). More precisely, if the predicted CFA is above a certain threshold and the predicted TTS is below another threshold, then the policy rules the exercise as “below” the ZPD, thus too easy, and recommends skipping it. Similarly, the policy will skip

(a) Non-bonus exercises.

(b) Bonus exercises

Figure 1: The Zone of Proximal Development by CFA and TTS predictions. (a) demonstrate the stipulated ZPD and the skipping policy for regular (non-bonus questions), while (b) represents it for bonus questions.

a bonus exercise that is too challenging by the predictive models, to prevent the overwhelming of struggling students.

In addition, we adjusted E-gostky to handle “bad skips” (i.e. exercises that the policy would have skipped but the student had a hard time solving, meaning, not correct on the first attempt or took longer than the average time to solve the exercise). If a student does not solve correctly at first attempt an exercise that followed a skip, E-gostky sends her backwards in the curriculum, to the exercise that would have been presented, if there were no skips.

The policy also respects signals from content providers. For example, the content provider can flag an exercise as mandatory, in which case the exercise will be served to all students. Also, to improve future decisions and restrain the engine from making too many skips, with a certain probability, an exercise will be served to the student even if the policy described above suggests that it should be skipped.

To configure features the system uses at run-time, thresholds used for the skipping policy and the DA models were learned using offline data. This data was collected during the previous school year when 714 students were learning using the same content, but without the adaptive engine. We also used this data for the offline validation of the skipping policy, where we found that in comparison with other skipping policies (such as random skips and uniformly skipping after n consecutive successes), the chosen policy can save more time for the student while making fewer “bad skips”. During the offline evaluation, the thresholds of the system and the number of candidate exercises to skip were empirically selected. Tuning these parameters allowed adjusting the boundaries of the predicted ZPD. See [13] for more details about the methods used.

4. THE EDUCATIONAL CONTENT

The content was developed by pedagogical experts in the Center for Educational Technology (CET), with the goal of teaching fractions to 4th grade students. A learning path was provided, which is termed as the “baseline path”, designed by pedagogical experts. The content includes exercises, intertwined with interactive explanations and aids, and quizzes that are administered at the end of each section and used to assess mastery. A student can make as many attempts as needed to solve an exercise, and proceed to the next one.

5. IN-CLASS EXPERIMENT

The methods described above were implemented as a web-service that operates as follows. When a student solves an exercise, a request for the next exercise is sent from the content delivery system. E-gostky predicts the CFA and TTS for the following exercises and the policy is used to choose the next exercise to serve. The student is notified of the number of exercises skipped.

This service was deployed as part of an experiment including 412 students from 18 classrooms from 8 schools. Unfortunately, in 4 of the 8 schools, the data collected was invalid for the statistical analysis. This left 4 schools and 213 students for analysis purposes. The analysis considered the first two sections of the educational program where 60% of the students were using E-gostky and the rest were using the baseline approach as designed by the content provider.

6. EXPERIMENT RESULTS

In what follows, we compare the performance of students who learned using E-gostky, with those who learned with the baseline path. To control the classes' effect, we conducted a two-way ANOVA test. In cases where the assumptions to this test were not met, we used a Man-Whitney-U two-tailed test to compare both groups within each school separately and then used Bonferroni correction to get a corrected p -value for the entire test.

Total time spent. The total time spent is the sum of the time that the student spent on all of the exercises she was asked to solve. Students using E-gostky finished the exercises of the first two parts of the educational program 17% faster than the students in the baseline path (p -value = 0.025).

Time to solve an exercise. Students on the baseline path used less time on individual exercises but the difference is not statistically significant (p -value = 0.086).

Success Rate at First Attempt. In non-quiz questions, students' success rate in the adaptive path was significantly lower (p -value = 0.010) than that of the baseline students.

These results show that the E-gostky system worked as expected: skipping exercises that are likely to be answered correctly and fast to keep the students in their ZPD.

Quiz grades. To investigate E-gostky's effect on students' performance, we compared the students' average scores in two quizzes given to the students after completing the first and second units of the learning material. For quiz 1, the grades of the baseline group were higher, and this difference was borderline significant (p -value = 0.049) while in the second quiz there were no significant differences (p -value = 0.386). Since the groups were assigned randomly, it might be possible that the BL and ADL groups were not balanced. Hence, we evaluated the improvement rate between the quizzes. The adaptive group's mean improvement was higher, but only borderline significantly (p -value = 0.06).

A paired t-test was used to compare the probability to succeed on each question for each school separately. In both quizzes, the baseline path students' grades were significantly

higher (p -value = 0.008 \ 0.002 for the 1st \ 2nd quiz). However, when excluding School 4 from the analysis, the grade differences for quiz 1 are not significant (p = .108). This is not true for quiz 2 where in that case, the differences remain significant (p = .008).

The fact that the improvement rates are better for the treatment group (non significant) while the quiz scores are somewhat better for the control group may imply that the assignment of students to the treatment conditions was biased. Moreover, since some statistical tests show the differences in the scores to be significant while other tests do not, suggests that the differences, even if existent, are not big and may be controlled by tuning the skipping policy.

Guessing Rates. To compare guessing rates, we first set a time-limit threshold (see [13] for further details on the threshold selection). Questions which were answered faster than this threshold were regarded as guesses. Students using E-gostky guessed on average 25% less compared to the students in the baseline path. We found that both the treatment and the school had significant effects (p -value < 0.0001 in both cases), while the interaction effect was non-significant. The lower guessing rates in the adaptive path indicates that the students using E-gostky were more engaged, as suggested by previous studies [7].

6.1 Qualitative Results

Feedback from the teachers and students was gathered by face-to-face meetings or by phone interviews. The feedback reports reveal that the students enjoyed the overall experience of learning via a computerized environment. Besides that, they expressed special interest in working with the adaptive engine.

Engagement and motivation. The students reported that learning with E-gostky, which they nicknamed "the skipping engine", was more engaging and motivating, as two of the students mentioned, "I thought longer before answering each question, ... then I succeeded more and it skipped more questions for me...", "it gave me motivation to continue and I started to be more accurate...". This behavior was noticed by teachers: "There are children who came to class even in their free time".

Confidence and Self-efficacy Another important aspect of E-gostky is the immediate feedback the student received. It made them more confident about their proficiency and future success. "...It gave me a feeling that I know the material and that I can succeed each and every time", "... it gave me more confidence as I was advancing and the feeling that I have a better understanding of the material".

Usage of aids. Another effect of E-gostky was that to achieve more skips, the students showed a higher usage of aids to increase their accuracy in solving exercises. As one of the students reported, "...I used the lab more often and then I succeed more and then I got more skips".

7. DISCUSSION

The results show that students using E-gostky made similar progress between quizzes as did students in the control group. With that said, E-gostky saved ~ 17% of the time

for the students that were using it. The time saved, which is about $\frac{1}{6}$ of the time reserved for working with this e-learning system, can be used by teachers for other learning activities.

It might seem counter-intuitive at first glance that the students on the adaptive track spent more time on each exercise while their total time spent is smaller, but this is the result of E-gostky skipping over many easy exercises that the student would have solved fast. As Vygotsky's theory suggests, these exercises do not contribute to the learning process since they are not in the ZPD.

Another benefit of E-gostky is that the positive feedback students receive dissuades students from guessing, and motivates them to be accurate and as a result, further enhances learning [1, 2].

There are some limitations to the experiment we conducted. We see differences in the scores achieved in the first quiz between the groups. These differences are influenced by one particular school in which the differences are significant. However, we learned, by interviewing the teachers after the experiment, that some of them did not fully understand the adaptive mechanism and thought that exercises were skipped by mistake. This confusion was also reported in students' feedback: "At first I thought it was a bug in the software, so I went backwards to do skipped questions...", "In the beginning I thought there was something wrong with the system, so I went back to the questions it skipped...". We also note that some statistical tests indicate differences in the performance of the baseline group and the treatment group. However, there are indications that these differences may be due to biased assignments of students to the groups.

It is hard to distinguish between the contribution of exercise selection and the contribution of the notification students received about skipped exercises. Students learned that by providing accurate answers, the system will skip over exercises and this was considered as positive feedback. We conjecture that both factors contributed to the positive results of our system. However, quantifying the contribution is beyond the scope of this study.

8. CONCLUSIONS

We developed an adaptive learning engine, E-gostky that relies on Vygotsky's Zone of Proximal Development. E-gostky uses machine learning models to skip content in the learning curriculum by dynamically assessing the learning potential of the student at the current time. It was evaluated in a large-scale field experiment and compared to a baseline path which was built by domain experts. Results show that students using E-gostky maintained comparable performance while spending 17% less time, guessed less and reported higher engagement and motivation.

ABSTRACT

We present and evaluate a machine learning based system that automatically grades audios of students speaking a foreign language. The use of automated systems to aid the assessment of student performance holds great promise in augmenting the teacher's ability to provide meaningful feedback and instruction to students. Teachers spend a significant amount of time grading student work and the use of these tools can save teachers a significant amount of time on their grading. This additional time could be used to give personalized attention to each student. Significant prior research has focused on the grading of closed-form problems, open-ended essays and textual content. However, little research has focused on audio content that is much more prevalent in the language-study education. In this paper, we explore the development of automated assessment tools for audio responses in a college-level Chinese language-learning course. We analyze several challenges faced while working with data of this type as well as the generation and extraction of features for the purpose of building machine learning models to aid in the assessment of student language learning.

Keywords

Audio Analysis, Automatic Grading, Machine Learning

1. INTRODUCTION

Learning proper pronunciation is an essential aspect of learning to speak a new language. Almost all standardized language tests involve a section where the person being evaluated is expected to speak out loud; these verbal tests are used to assess student skill and knowledge of pronunciation, fluency, and the correct usage of vocabulary. In the previous years, computer-assisted pronunciation teaching (CAPT) has

gained attention and has been commercialized such as Pearson, SRI, and ETS [6]. Language learning is a common part of many educational systems, and language classes often involve assignments which are related to speaking tasks. This gives us, as researchers and developers of tools to aid in the teacher assessment of students, an opportunity to collect and utilise language students' audio responses. The audio data of language learners are rich data-sets which provide insights about how well students are acquiring language skills based on the pronunciations and quality of speech. These data-sets may also identify problem areas where a student may be in need of improvement. However, collecting this data can be challenging because the data is not commonly stored uniformly and all in one place. Since oral tests are given in class, recording and storing this data would add an overhead to the teacher's responsibilities. Additionally, this process can occur more efficiently. The students are all evaluated for on similar measures like the standardized exams that test pronunciation and fluency. By automating the process of grading students, we can both help learners self-evaluate their progress and provide tools to teachers who traditionally grade students by listening to audio files (a task that can be very time consuming considering the number of potential students a teacher may have in a single class). The grading systems which have been researched previously are usually for more closed-form responses. Open ended responses, such as essays or explanatory, answers are a more challenging task to automatically grade, but there has been growing research on developing automated assessment tools for such tasks [5].

This paper presents an exploratory analysis representing an initial step toward developing automated assessment tools for language learning audio responses. In this paper, we explore the development of automated graders of student audio responses from a Chinese language class. We seek to address the following research questions: 1. By employing models of varying complexity, are we able to automatically grade student audio responses better than a simple majority class baseline model? 2. Does a recurrent deep learning model outperform a static decision tree model in regard in predicting student grades? 3. Which features extracted from student audio responses provide the greatest impact on model performance in predicting student grades?

2. RELATED WORK

Automatic speech recognition systems have been the focus of several works over the past three decades. Some of this notable research has been conducted on the use of Automatic Speech Recognizer (ASR) technology for automatic speech scoring and the evaluation of pronunciation quality (cf. [7]). With Deep Learning improving the performance of many tasks, it has been widely used in the Automatic Speech Recognition and Scoring tasks [4]. Many states have begun to use computer-based English Learning Proficiency (ELP) assessments, which has led to a growing interest in automated scoring of spoken responses to increase the efficiency of scoring. However, there is a dearth of systems which grades foreign language learners. In this paper we plan to focus on Chinese learning Undergraduate students.

3. DATASET

The data-set is collected from a Chinese language class for undergraduate students in a university located in the North-East region of the United States. The data collected consists of 63 distinct students from 3 classes run between 2017 and 2019. All of these classes were taught by the same instructor. The data is comprised of 60 audio recordings which includes audio responses from 3 different prompts. The average length of the audio is approximately 2.5 minutes. All work is submitted through an institute-hosted learning management system from which the teacher then downloads all the files in order to listen and grade each student's work. In our data-set, the teacher followed a rubric when assessing each student that is reported in Table 1

3.1 Pre-processing

A series of pre-processing steps were applied to the raw audio responses for use in this work. Among the 60 responses, in 12 cases, responses included multiple students speaking; it is likely that permission was given to these students to work collaboratively on the assignment. In 2 of these cases, a separate grade was given to each student present in the recording while in the remaining 9 cases, the students involved were given the same score. We observed that the grades in these 2 cases where the score differed did not vary more than 1 point (on a scale of 11, from 0-10 inclusively), and therefore we aggregated each of the responses and grades into a single instance by averaging the two scores. The other 9 cases were left as individual samples, leaving us with the aforementioned 60 distinct responses for use in our models. For the feature extraction step (described in the next section), we further need to convert our audio data in a mono-channel format. The data we collected contains stereo data (i.e. it contains a separated right and a left channel). To convert each response to a mono signal, we took the average of the two channels of the stereo data.

Grading Components	Percentage
Rich Content	40%
Grammar and word usage	20%
Accuracy of tones and pronunciation	20%
Fluency	20%

Table 1: The grading rubric used to assess student audio responses.

4. METHODOLOGY

Our methodology includes feature extraction and building models for predicting teacher-provided grades for student audio responses. We compared two non-linear models to a simple baseline. While the grade labels were provided on an 11-point scale (0-10), this scaling is non-linear due to non-uniformity across the grades (the average grade was 7.41). Since few of the assignments were graded on different scales, a min-max scaling was used to transform all the scores into a scale of 0-10.

4.1 Feature Extraction

Audio feature extraction is performed to transform the audio signals recorded in the .wav files into a representation which can be used for machine learning. The features used are extracted using the *PyAudioAnalysis* library; this is a python-based library which is exclusively used for audio data feature extraction. We use the default parameters of 50 milliseconds and 25 milliseconds for the window size and step amount respectively. With these parameters, the feature extraction function split the input signal into short windows (frames), leading to a sequence of short-term feature vectors at regular intervals within the signal. The number of windows varied for each of the signals based on the length of the audio file. The features extracted for use in this work are briefly described in Table 2. For each time window, we extracted the 34 features, where several of the features described in Table 2 are described using a multi-valued numeric vector indicated through the Feature ID column.

4.2 Deep Learning Model

The sequential and temporal aspects of audio data makes the application of a recurrent deep learning model an appropriate choice for developing automated assessment tools. Specifically, we utilize a Long Short Term Memory (LSTM) [3] network, as it is designed to model complex temporal relationships within sequential data. This model observes a sequence of time steps (e.g. frames of audio as described in the Feature Extraction Section) and is trained to produce a single value corresponding to the estimated grade for the student response. Due to the number of features and length of each student response, we chose a network structure with 3 hidden layers. The input of the model is represented as a sequence of 34-valued vectors corresponding with the extracted features, which is then passed to a LSTM hidden layer of 50 nodes, before being passed through 2 additional fully connected non-recurrent layers of 100 units each. An output layer of a single node is used corresponding with the grade of the student, treated as a regression rather than a classification task. We chose this structure to prevent the network from overfitting due to the long sequences (i.e. by using a smaller LSTM layer), but providing enough depth in the model to learn feature representations from each sequence; exploring additional model structures is planned for future work. The LSTM looks at each frame and provides an estimated grade for it, but is only updated and evaluated on the final frame of the sequence. We applied a 5-fold cross validation on the data-set and measure performance using RMSE and Spearman correlation.

4.3 Decision Tree Model

To contrast the deep learning network, we also compare a decision tree model which has the capacity to learn non-linear

Feature ID	Feature Name	Description
1	Zero Crossing Rate	The rate of sign-changes of the signal during the duration of a particular frame.
2	Energy	The sum of squares of the signal values, normalized by the respective frame length.
3	Entropy of Energy	The entropy of sub-frames' normalized energies. It can be interpreted as a measure of abrupt changes.
4	Spectral Centroid	The center of gravity of the spectrum.
5	Spectral Spread	The second central moment of the spectrum.
6	Spectral Entropy	Entropy of the normalized spectral energies for a set of sub-frames.
7	Spectral Flux	The squared difference between the normalized magnitudes of the spectra of the two successive frames.
8	Spectral Rolloff	The frequency below which 90% of the magnitude distribution of the spectrum is concentrated.
9-21	MFCCs	Mel Frequency Cepstral Coefficients form a cepstral representation where the frequency bands are not linear but distributed according to the mel-scale.
22-33	Chroma Vector	A 12-element representation of the spectral energy where the bins represent the 12 equal-tempered pitch classes of western-type music (semitone spacing).
34	Chroma Deviation	The standard deviation of the 12 chroma coefficients.

Table 2: The 34 Features extracted from the audio along with its description.

relationships between the features and teacher-provided grades, but does so in a non-sequential manner. As such, we needed to aggregate the audio features into a single vector that describes the response as a whole as input to the model. We took the average across each of the 34 features across each response and used it to predict the teacher-provided grade. We applied a decision tree regressor using the CART algorithm [1]. Similar to the deep learning model, we evaluated the model using a 5-fold cross validation using measures of RMSE and Spearman correlation. Within each training fold we optimized it for its depth using the training data.

4.4 Baseline Method

We compare each the LSTM model and decision tree model to a simple baseline using a majority class model. For this method, we take the average grade provided by the teacher and use this as a prediction for every sample. It can be used to evaluate how well our models perform in comparison to a model that incorporates no audio information.

5. RESULTS

We report model performance using measures of RMSE, a measure of prediction error, and Spearman correlation (Rho). The performance of each of our models in predicting the audio response grades is reported in Table 3. From this, it can be seen that both models outperform the baseline model in regard to RMSE, but only the LSTM model exhibited positive correlation. These results demonstrate that the LSTM is the superior model, although the values suggest that there is still room for improvement. As the grade labels follow a 10 point scale, the best RMSE of 2.728 exhibited by the LSTM suggests that it is, on average, over- or under-predicting the true grade of the student by just under 3 grade points. Despite this room for improvement, the results do suggest that both the LSTM and decision tree models are learning from the data in potentially different ways. We further explore each of these models through an ablation study.

6. ABLATION STUDY

In this experiment, we perform an ablation study where we run a model with all the features and iteratively remove

Model	RMSE	Rho
Majority Class	3.323	-
Decision Tree	2.807	-0.076
LSTM	2.728	0.163

Table 3: Audio Grade prediction: average 5-fold RMSE and R2 score for the models

each to observe impacts to model performance. Changes in model performance as a result of removing a feature can be used then as a measure of feature importance in determining the grade of the student. Table 4 reports the results of this study across both the LSTM and Decision Tree models. The rows in the table are sorted to reflect the features of highest impact found in regard to changes in RMSE for the LSTM model as this was the highest performing model across both metrics.

In regard to the decision tree model, the 3 features which cause the largest drop in RMSE are Energy of the wave, MFCC features, and Spectral Centroid. With respect to the Spearman correlation metric, the top three correlated features are the Chroma features followed by the Zero Crossing Rate and MFCC features. In the LSTM model, the 3 features which cause the largest decrease in the RMSE are the 12 Chroma features, the Energy Entropy, and the Zero Crossing Rate feature. However, comparing the Spearman's correlation measure (rho) does not follow the same trend as the RMSE. In the case of LSTM, most of the models have a rho value more than the model with all the features. This may suggest overfitting within the model, particularly as some of the features similarly lead to improvements in RMSE when removed.

7. DISCUSSION

As can be seen from the decision tree model as well as the LSTM model, the energy related features has a significant impact on the evaluation of the pronunciation. In [2] it was shown that 'formants' are bands of energy around a particular frequency which characterizes different resonances of the vocal tract and it helps understand pronunciation of vow-

Feature Removed	LSTM		Decision Tree	
	Delta RMSE	Rho	Delta RMSE	Rho
Chroma	0.118	0.172	0.217	0.162
Entropy of Energy	0.076	0.18	0.143	0.074
Zero Crossing Rate	0.042	0.149	0.132	0.121
Spectral Centroid	0.042	0.148	0.226	0.072
Spectral Spread	0.04	0.189	0.205	0.085
Spectral Rolloff	0.028	0.206	0.136	0.107
Spectral Entropy	0.025	0.217	0.132	0.121
Chroma Deviation	0.018	0.208	0.059	0.076
Energy	-0.011	0.19	0.361	-0.025
Spectral Flux	-0.016	0.242	0.151	0.11
MFCC	-0.18	0.161	0.314	0.132

Table 4: Ablation Study results from the LSTM and Decision Tree model

Figure 1: The Waveform from an audio of a student answer along with the predictions by the LSTM model at each window.

els. The second feature that has an impact in the decision tree is the MFCC feature. The MFCC features accurately characterizes the envelope of the short time power spectrum which manifests the shape of the vocal tract. Hence it makes sense that it influences the pronunciation score. However, the LSTM model seems to understand MFCCs differently and hence, the removal of these MFCC features seem to having a improvement in the model. Further analysis on the MFCC features can help us understand why this is the case. The Chroma feature provides information related to the 12 musical octaves. Both the LSTM and the decision tree model seem to show an increase in the RMSE when these features are removed.

A benefit of the sequential structure of the LSTM model is its ability to illustrate the development of its grading estimates over the audio response. From moment-to-moment, a grade estimate can help to indicate sections of the audio response that suggest a high grade (e.g. well-pronounced words) and sections that suggest a low grade (e.g. poor pronunciation or areas of silence); an example of this is illustrated in Figure 1. In this figure, the bottom image depicts the wave form of a student audio response while the top figure illustrates the LSTM estimate over the length of the response. Such a report could help teachers to identify sections of audio where the student may be in need of additional aid.

8. CONCLUSION AND FUTURE WORK

Based on the results we plan to follow the following steps for the future. First, exploring additional model architectures may lead to more accurate assessment tools. Second, we plan on incorporating contextual knowledge since 40 percent of the grade includes content. Converting the audio to text and extracting text-related features could potentially provide more understanding of the evaluation of the audio. And finally, using LSTMs the scores for each segment of audio can be graded and we plan on using it to aid students in self-assessment and to help teachers learn where their students need further aid. This work is an initial step toward the development of automated assessment tools designed to aid language learning students and teachers. We hope that further in-depth analyses of different combinations of the features will better help understand these relationships.

ABSTRACT

We introduce ml-BERT, an effective machine learning method for automatic short answer grading when training data, i.e., graded answers, is limited. Our method combines BERT (Bidirectional Representation of the Transformer), the state-of-the-art model for learning textual data representations, with meta-learning, a training framework that leverages additional data and learning tasks to improve model performance when labeled data is limited. Our intuition is to use meta-learning to help us learn an *initialization* of the BERT parameters in a specific target subject domain using unlabeled data, thus fully leveraging the limited labeled training data for the grading task. Experiments on a real-world student answer dataset demonstrate the promise of ml-BERT method for automatic short answer grading.

1. INTRODUCTION

We consider the problem of automatic grading for short answer questions that require students to provide concise *textual* responses. Figure 1 shows an example of short answer questions. The pedagogical benefits of these questions over multiple-choice questions have been studied and validated by [11]. Unfortunately, manually grading short answer questions is labor intensive, rendering it extremely challenging to administer these questions in large-scale educational settings.

In this paper, we aim to advance the state-of-the-art in automatic short answer grading. This problem can be viewed as a supervised (machine) learning problem where we would like to grade (classify) answers as correct or incorrect given a dataset of answers and their grades (labels).¹ A method capable of reliably grading short answer questions gives instructors more freedom in choosing the form of assessments in large-scale educational settings where

¹We will use “grade” and “label” interchangeably throughout the paper.

Question:	What is a difference between saturated and unsaturated fats?
Answer:	Saturated fats have no double bonds whereas unsaturated fats have at least one double bond

Figure 1: A sample question and correct student answer in their raw textual form taken from a high school biology class.

manual grading is unfeasible. In practice, however, the number of graded answers is very limited since manual grading is labor-intensive. This constraint makes training a classifier for automatic grading a highly challenging task. Thus, it is desirable to develop a method that can effectively leverage the ungraded answers to learn a representation of the answers and achieve satisfactory performance with only a few graded answers. This feature is valuable for instructors in large-scale educational settings because they would need to manually grade only a few answers, which saves them time and effort that are better allocated to other pedagogical actions. Therefore, in this work, we focus on this particular scenario where we only have access to a limited number of graded answers.

A number of prior works have demonstrated the effectiveness of machine learning methods in automatic grading [2, 8, 9, 10]. As a high-level summary, a typical method first converts textual data composed of questions and answers to some vector representations and then uses them to classify an answer as correct or incorrect. In our problem setting, however, this method for automatic short answer grading faces two major challenges. First, we need a *model* capable of producing high quality representations of textual data that captures the information in both the question text and the answer text, which is essential for the classifier to make its decision. We note that learning a representation of textual data has been a challenge not only for short answer grading but also for the broader field of natural language processing (NLP). Second, since the number of graded answers is limited, we need a specialized *training procedure* that enables the classifier to remain effective using only a limited number of labels. We note that this procedure is important because a number of prior works, e.g., [4], have demonstrated that regular training procedures may result in poor results when labeled data is limited. For example, we have merely less than 20k labeled answers whereas related classification tasks such as sentiment analysis have over 1 million labeled examples [5], which contributes to the success of machine learning models on those tasks.

Zichao Wang, Andrew Lan, Andrew Waters, Phillip Grimaldi and Richard Baraniuk "A Meta-Learning Approach to Automatic Short Answer Grading" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 667 - 670

To tackle the first challenge and learn textual data representations efficiently and effectively, we resort to BERT (bidirectional encoder representation of the transformer), the state-of-the-art model for text. Since BERT achieves the best results to date in a wide range of benchmark NLP tasks, we develop our method on top of it. To tackle the second challenge and fight the scarcity of labeled data, we resort to *meta-learning*, an emerging training procedure that searches for a good initialization of the model parameters by using unlabeled data to optimize additional objectives that are unrelated to the target task. Previous studies [4, 7] have shown that parameter initialization is critical for the success of neural network models including BERT; Thus, the meta-learning procedure helps us to find a better initialization of the model parameters and quickly adapt to new tasks with only limited labeled data.

1.1 Contributions

We propose ml-BERT, a meta-learning method that augments the bidirectional encoder representation of the transformer (BERT) model for automatic short answer grading with limited labeled answers. Our method consists of two learning phases. First, in the meta-learning phase, we optimize for an initialization of BERT parameters using unlabeled data. We carefully choose data from a specific educational domain to use in the meta-learning phase such that it is closely related to the questions in the short answer grading task. This choice ensures that the meta-learned initialization builds a good representation of the domain and is highly useful to the subsequent short answer grading task. Second, in the regular learning phase, we optimize BERT parameters for the short answer grading task using limited labeled training data, starting from the meta-learned parameter initialization in the previous phase. Experimental results on a real-world dataset consisting of student answers to a set of questions in high school biology shows that the proposed ml-BERT method is more effective than regular BERT and several other baseline methods when labeled data is limited.

The rest of the paper is organized as follows. Section 2 details our ml-BERT method. Section 3 presents experimental results on a real-world student answer dataset and discusses the key findings. Finally, Section 4 summarizes our work and proposes future research directions. This paper is a truncated version; for more details including background on BERT and meta-learning, exhaustive literature review and additional experimental results, please refer to the long version of this paper on ArXiv with the same title.

2. METHOD

In this section, we describe ml-BERT, our novel training procedure that augments BERT with meta-learning for short answer grading. The ml-BERT training procedure consists of two learning phases, namely, the *meta-learning phase* and the *regular learning phase*. In the meta-learning phase, we optimize for an initialization of BERT parameters that ultimately leads to better short answer grading performance. In the regular learning phase, we optimize for the BERT parameters using labeled short answer dataset to further improve the model performance on short answer grading.

Key to the success of ml-BERT is the choice of datasets and tasks in the meta-learning phase for learning parameter initialization. We choose *language modeling* and *next sentence prediction* as our meta-learning tasks. We use a dataset that includes textbooks, question texts, and correct student answer texts for the language modeling task and a dataset that includes textbooks for the next sentence prediction task. The specific choice of the above data depends on the educational domain. For example, we would choose relevant

biology textbooks if the task is to grade answers to biology related questions. Intuitively, the language modeling task helps us learn an initialization that captures the nuances of the language usage specific to each educational domain. The next sentence prediction task helps us learn an initialization that captures the logic flow underlying the textbooks from which questions are asked. Initialization learned from the above tasks and data is thus informative to the subsequent short answer grading task because it contains some knowledge of whether an answer uses appropriate language and whether an answer is logically related to its associated question and the specific educational domain.

Below, we first formally define the target task which is short answer grading. We then describe the two meta-learning tasks and their datasets. Finally, we present the full ml-BERT training procedure.

Target task: short answer grading. This is a supervised learning problem that we explicitly train the model to perform well on. The training dataset for short answer grading consists of N examples $\{q_i, a_i, y_i\}_i^N$, where q_i and a_i are text segments representing question and student short answer, respectively, and y_i is a binary variable indicating whether the answer is correct or incorrect. The learning objective is to correctly classify each answer given the question. We use the negative log-likelihood loss to measure this objective:

$$\mathcal{L}_T = -\frac{1}{N} \sum_{i=1}^N \log p(y_i | a_i, q_i) \quad (1)$$

where $p(y_i | a_i, q_i)$ is modeled by a composition of functions including BERT mapping $f^{(1)}(\cdot)$ of the first “[CLS]” token (see Section 2.1 of the long version of this paper),² a fully connected layer $g : \mathbb{R}^M \rightarrow \mathbb{R}$, and a sigmoid function $\sigma(\cdot)$:

$$p(y_i | a_i, q_i) = \sigma \left(g \left(f^{(1)}(a_i, q_i) \right) \right).$$

In practice, in order to obtain a single textual input for BERT, we append all tokens of each answer a_i to all tokens of its associated question q_i , append “[CLS]” and “[SEP]” respectively at the beginning and end of the concatenated token sequence, and separate the answer and question tokens with “[SEP]”.

Meta-learning task #1: language modeling. This is an unsupervised learning problem. The dataset $\mathcal{D}_1 = \{s_i\}_{i=1}^{N_1}$ consists of a collection of N_1 sentences s_i taken from text corpora specific to the educational subject. Each sentence is represented by a sequence of J_i tokens: $s_i = \{w_j\}_{j=1}^{J_i}$ (see Section 2.1 of the long version of this paper).

During training, we randomly replace a portion of all tokens in each sentence with the special token “[MASK]” and ask the model to predict these masked tokens. We set the portion of masked tokens to 15% for each sentence. Performance of token prediction is measured by negative log-likelihood loss \mathcal{L}_1 as:

$$\mathcal{L}_1 = -\frac{1}{N_1} \sum_{i=1}^{N_1} \sum_{k=1}^{J_i} \log p(w_{ik} | w_1, \dots, w_{ik-1}, w_{ik+1}, \dots, w_{J_i}) \quad (2)$$

where w_{ik} represents the k^{th} masked token in the i^{th} sentence. The conditional probability distribution is modeled using the composition of BERT mapping $f(\cdot)$, a linear layer $g_i : \mathbb{R}^M \rightarrow \mathbb{R}^V$

²In BERT, we obtain the sentence representation by querying the embedding of this “[CLS]” token.

Table 1: Statistics of the dataset for each task. Note that the short answer grading dataset consists of only labeled answers which represents less than 10% of all available answers.

tasks	#examples	#average tokens
Short answer grading	495 questions 18143 answers	17.88 per question 12.31 per answer
Masked language modeling	78684 sentences	19.08 per sentence
Next sentence prediction	21052 sentences	25.54 per sentence

that maps every BERT encoded token into a vector of dimension V which is the size of the vocabulary, and a softmax function:

$$p(w_k | w_1, \dots, w_{k-1}, w_{k+1}, \dots, w_J) = \text{softmax}(g_1(f(\tilde{s})))$$

where we drop the example index i for notation simplicity. \tilde{s} denotes the input sentence with the k^{th} token replaced by the mask which indicates which token the model should predict.

We note that there are other strategies for language modeling with BERT. Conventionally, one models language by predicting the next token in the input sentence given all previous tokens [6]. We choose this *masked* prediction strategy for language modeling because of its superior empirical performance than the conventional approach [3].

Meta-learning Task #2: next sentence prediction. This is an unsupervised learning problem. The dataset $\mathcal{D}_2 = \{s_i, \hat{s}_i, z_i\}_{i=1}^{N_2}$ consists of N_2 pairs of sentences sampled from textbook chapters specific to the educational subject of the short-answer questions. We sample the sentence \hat{s}_i such that half of the time it is the next sentence of s_i and half of the time it is a sentence from a random location in the textbook. z_i is a binary variable indicating whether \hat{s}_i is the next sentence of s_i . We use negative log likelihood \mathcal{L}_2 to measure model performance on next sentence prediction:

$$\mathcal{L}_2 = -\frac{1}{N_2} \sum_{i=1}^{N_2} \log p(z_i | s_i, \hat{s}_i) \quad (3)$$

where the conditional probability is modeled by the composition of BERT mapping $f^{(1)}(\cdot)$ of the first “[CLS]” token, a fully connected layer $g_2: \mathbb{R}^M \rightarrow \mathbb{R}$, and a sigmoid function $\sigma(\cdot)$:

$$p(y_i | s_i, \hat{s}_i) = \sigma \left(g_2 \left(f^{(1)}(s_i, \hat{s}_i) \right) \right).$$

The ml-BERT training procedure. Model parameter update according to ml-BERT proceeds as follows. In the meta-learning phase, we update the BERT parameters by alternating between the two tasks until we reach a pre-specified stopping condition. In the regular learning phase, we initialize the BERT parameters from the meta-learned parameter initializations in the previous phase and update the parameters using the labeled short answer dataset until we reach a pre-specified stopping condition. In both phases, we perform parameter update using gradient descent optimizers. The exact choice of the optimizer is flexible; we use the customized Adam optimizer for BERT outlined in [3]. The proposed ml-BERT procedure is simple to implement and effective in practice, which we demonstrate in the next section.

3. EXPERIMENTAL RESULTS

We now demonstrate the effectiveness of our method using real-world data. We first introduce various model and training settings

and then explain our results in detail. Code for our experiments can be shared upon request.

Dataset and pre-processing steps. We collect real-world short answers from semester-long biology classes that use the OpenStax Biology textbook.³ Table 1 summarizes the key statistics of the dataset. Notably, only about 10% of the answers are graded; we use only the graded responses as training data. Heaping the power of the vast number of ungraded responses is left for future work. We perform an 80/20 training/validation split independently for each question. We also discard questions in the training set with less than 20 labeled answers, 10 for each label, and questions in the validation set with less than 4 labeled answers, 2 for each label. This is to ensure we have well-balanced training and validation splits of the dataset. For the language modeling task during meta-learning, we use all textbook text, questions, instructor-authored answers associated with the OpenStax Biology textbook. For the next sentence prediction task, we only use the textbook text.

The textual data is minimally pre-processed. We first turn all texts to lowercase. For BERT, we use the WordPiece tokenizer to process the input text into a sequence of tokens. For other baseline models, we use a bag-of-words (BoW) representation of textual data, which involves a more complicated pre-processing pipeline including tokenization, lemmatization and stop word removal.

Hyper-parameters. We adapt the standard BERT model configuration and training setup. We use BERT’s customized Adam optimizer with a learning rate of 3×10^{-5} . Training lasts 10 epochs with a batch size of 32. Each question-answer pair is limited to 128 word pieces; shorter ones are padded and longer ones are truncated. Most of the setup information is available in the official BERT code release.⁴

Baseline models. We compare ml-BERT with four baseline methods: 1) baseline BERT without meta-learning, 2) Random Forest, 3) K-Nearest Neighbors and 4) logistic regression. The baseline BERT model has the same hyper-parameter setup as BERT with meta-learning. We use default settings in the python `sklearn` package for the remaining three models. In addition, logistic regression is the best linear classifier among those that we tested; therefore we use logistic regression as the representative linear classifier baseline.⁵

3.1 Quantitative Analysis

Table 2 compare the classification accuracy and F1 score of ml-BERT to that of the four baseline models on the validation set. We clearly see ml-BERT improves both classification accuracy and F1 score compared to the baseline models. Note in particular that BERT without meta-learning only achieves comparable performance with random forest, but with meta-learning it is able to outperform all baseline models. This suggest that in the limited labeled answer scenario, meta-learning has the potential to lift the model performance further.

To get a fine-grained performance analysis, We compare the performance of ml-BERT and BERT on questions of different levels according to Bloom Taxonomy. Bloom Taxonomy [1] categorizes

³<https://openstax.org/details/books/biology>

⁴<https://github.com/google-research/bert>

⁵Recall that K-Nearest Neighbors and Random Forest are nonlinear classifiers.

Table 2: Evaluation accuracy and F1 score comparing ml-BERT with various baselines.

Models	eval. acc.	eval. F1
Logistic Regression	71.39%	0.723
K Nearest Neighbors	72.74%	0.735
Random Forest	77.82%	0.768
Baseline BERT	77.80%	0.788
ml-BERT	80.17%	0.815

Figure 2: Grading accuracy per Bloom level comparing ml-BERT to BERT. We see improved accuracy across questions with different Bloom’s levels.

questions into 6 distinct levels where higher level indicates more cognitive load required to answer a question. We can thus use Bloom levels as rough difficulty measure of the questions. Figure 2 summarizes the classification accuracy for each bloom level. We see that ml-BERT outperforms BERT in grading questions across all bloom levels, most significantly at Bloom level 5. This can be explained by the benefit of meta-learning which learns language patterns and logical relations in the specific educational subject that helps grade these “difficult” questions with higher accuracy.

3.2 Influence of Each Meta-Learning Task

We investigate the effect of each of the meta-learning tasks on the quality of the learned representations of text. Specifically, we compare ml-BERT using both learning tasks with ml-BERT using only one of the learning tasks. We summarize the comparison in Table 3. Results suggest that, overall, both tasks contribute to the quality of the learned representations. We emphasize that, even with only one of the meta-learning tasks, ml-BERT is able to adapt to the short answer grading task and achieve better performance compared to baseline BERT. This observation highlights the importance of using task-specific data and tasks in the meta-learning phase. Moreover, it also suggests that ml-BERT has potential in further improving its performance as we incorporate more tasks specific to the target educational domain, which we leave for future work.

4. CONCLUSIONS AND FUTURE WORK

We have introduced ml-BERT, a method to augment the state-of-the-art text embedding model BERT with meta-learning to improve its performance on automatic short answer grading. In the first phase of ml-BERT, we use meta-learning to learn an initialization of BERT parameters by training language modeling and next sentence prediction tasks on data specific to the relevant educational domain. In the second phase, we further optimize the model parameters using limited labels on the correctness of the short answers. We experimentally validate the effectiveness of ml-BERT on real-world student answers collected in high school biology classes. Both quantitative and qualitative results demonstrate that the proposed method is promising.

Table 3: The impact of each of the two meta-learning tasks on grading accuracy. We see that the best results are achieved when we use both meta-learning tasks. We also observe that using either one of the meta-learning tasks already leads to improvement over baseline BERT.

Conditions	eval. acc.	eval. F1
ml-BERT		
- Without masked language modeling	79.12%	0.805
- Without next sentence prediction	78.63%	0.793

ABSTRACT

Knowledge tracing is an essential and challenging task in intelligent tutoring systems, whose goal is to estimate students' knowledge state based on their responses to questions. Although many models for knowledge tracing task are developed, most of them depend on either concepts or items as input and ignore the hierarchical structure of items, which provides valuable information for the prediction of student learning results. In this paper, we propose a novel deep hierarchical knowledge tracing (DHKT) model exploiting the hierarchical structure of items. In the proposed DHKT model, the hierarchical relations between concepts and items are modeled by the hinge loss on the inner product between the learned concept embeddings and item embeddings. Then the learned embeddings are fed into a neural network to model the learning process of students, which is used to make predictions. The prediction loss and the hinge loss are minimized simultaneously during training process.

Keywords

knowledge tracing, hierarchical structure modeling, deep learning

1. INTRODUCTION

Knowledge tracing is an essential and challenging task in intelligent tutoring systems. The goal of knowledge tracing task is to estimate the mastery state of a specific knowledge component based on students' responses to items. In other words, knowledge tracing aims to predict the correctness of a student's response to the next item according to all the previous response records.

In order for a student to answer an item correctly, he/she needs to master the concepts related to this item first. For example, a student can provide correct responses to both "1 + 1" and "28 + 36", which illustrates that this student may master the general concept of addition. Some existing knowledge tracing models [1, 8, 9] are proposed to predict the students' performance only based on general concept information of items. A common drawback of such models is

that they ignore the differences among different items even under the same general concept. In fact, if a student knows how to solve the items related to the concept "Addition of Two Integers", this student may correctly answer "28 + 36" but make a mistake when answering a harder item "285 + 361". In addition, the learning gains of answering different items related to the same concept are different. Correctly solving a more complex item indicates a higher gain towards the desired knowledge states than that obtained by solving an easier one. To distinguish and model the differences among items, Item Response Theory model [10] is proposed, which directly uses items as the input to estimate a student's ability. However, students may visit these online platforms very infrequently and only attempt on a small subset of items. Therefore, for each item in the dataset, only a small number of attempts are made, which leads to the issue of data sparsity. On such sparse data, existing knowledge tracing models, for example, Item Response Theory [10], that takes items as input may have limited performance. Deep knowledge tracing [9], which applies RNN to predict the performance of students, has shown improved prediction performance in knowledge tracing, but it requires a large amount of data for training. Such models would suffer more from the data sparsity issue.

To handle the data sparsity issue and better distinguish items, we propose a novel deep hierarchical knowledge tracing (DHKT) model, which can leverage the hierarchical information between items and concepts. Specially, DHKT learns the embeddings of items and concepts and models the relations among items and concepts by calculating the hinge loss of the inner product of the embeddings. The main contribution of this work can be summarized as follows: We propose a novel DHKT model by leveraging the hierarchical structure between items and concepts into the state-of-the-art deep knowledge tracing model. Experimental results show that the DHKT model learns meaningful representations and outperforms the state-of-the-art baselines.

2. METHODOLOGY

In this section, we first introduce how to model the students' learning process using a deep learning framework, and then illustrate how to incorporate the concept-item graph into the model.

2.1 Problem Formulation

We denote the set of students as \mathcal{K} . For a student $k \in \mathcal{K}$ interacting with the system t times, the interactions are denoted as $\mathcal{X}_k = \{x_{k,1}, x_{k,2}, \dots, x_{k,t}\}$. In this work, the inter-

Tianqi Wang, Fenglong Ma and Jing Gao "Deep Hierarchical Knowledge Tracing" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 671 - 674

actions specifically refer to the students' responses to corresponding items. $x_{k,t} = (i_{k,t}, y_{k,t})$ is a tuple representing the item $i_{k,t} \in \mathcal{I}$ attempted by student k at time t , where \mathcal{I} represents the set of all items, and $y_{k,t} \in \{0, 1\}$ represents the correctness of the response. $y_{k,t} = 0$ indicates an incorrect response and $y_{k,t} = 1$ represents a correct one.

These items are related to different knowledge concepts, which are the more general representations of the items. The set of knowledge concepts is denoted as \mathcal{C} in this work. The relations between items and concepts are annotated by experts. We denote the mapping matrix, i.e., the concept-item graph, as $\mathcal{Q} \in \{0, 1\}^{|\mathcal{C}| \times |\mathcal{I}|}$. If $q_{m,n} = 1$, which means the item n is related to the concept m ; otherwise, $q_{m,n} = 0$.

With the above definitions, the knowledge tracing task can be formulated as a binary sequence prediction problem: Given a series of interactions $\mathcal{X}_k = \{x_{k,1}, x_{k,2}, \dots, x_{k,t}\}$, $x_{k,t} = (i_{k,t}, y_{k,t})$ of a student k , the next item $i_{k,t+1} \in \mathcal{I}$ and the concept-item mapping matrix \mathcal{Q} , our goal is to predict the value of $y_{k,t+1}$ representing if student k will answer the new given item $i_{k,t+1}$ correctly based on the current knowledge state $\mathbf{h}_{k,t}$ of the student.

2.2 Model Student Learning

We use dense embeddings instead of one-hot encoding as the input of the DHKT model. These dense embeddings can be automatically learned from the training dataset. To distinguish the difference among items related to the same concept and preserve the concept-level information, the concatenation of item embedding and concept level embedding is employed to represent an item in the DHKT model.

Let $\mathbf{e}_{i_{k,t}} \in \mathbb{R}^d$ denote the embedding of the item $i_{k,t}$, where d is the dimension of the embedding. Since one item $i_{k,t}$ can be related to more than one concept, we use the average embeddings of all the concepts related to $i_{k,t}$ as its concept-level embedding $\mathbf{e}_{c_{k,t}}$. Mathematically, the concept-level embedding for the item $i_{k,t}$ is defined as:

$$\mathbf{e}_{c_{k,t}} = \frac{1}{|\mathcal{C}_{k,t}|} \sum_{c_m \in \mathcal{C}_{k,t}} \mathbf{e}_{c_m}, \quad (1)$$

where $\mathcal{C}_{k,t}$ denotes the set of concepts related to item $i_{k,t}$, $|\mathcal{C}_{k,t}|$ is the number of such concepts, c_m represents a concept in $\mathcal{C}_{k,t}$, and \mathbf{e}_{c_m} is the embedding of the concept c_m .

The new hierarchical representation of the item $i_{k,t}$ can be described as the concatenation of item and concept embeddings:

$$\mathbf{v}_{k,t} = \mathbf{e}_{i_{k,t}} \oplus \mathbf{e}_{c_{k,t}}, \quad (2)$$

where $\mathbf{v}_{k,t} \in \mathbb{R}^{2d}$ and \oplus denotes vector concatenation.

To jointly represent the item and the correctness of student k 's response, we introduce $\mathbf{a}_{k,t} \in \mathbb{R}^{4d}$ as:

$$\mathbf{a}_{k,t} = \begin{cases} \mathbf{v}_{k,t} \oplus \mathbf{0} & y_{k,t} = 1 \\ \mathbf{0} \oplus \mathbf{v}_{k,t} & y_{k,t} = 0 \end{cases}, \quad (3)$$

where $\mathbf{0} \in \{0\}^{2d}$ is the zero-vector. $\mathbf{a}_{k,t}$ is the input when we model the process of student learning.

In the student learning process, the current knowledge state of a student is highly correlated with the previous knowledge state and the learning gains from the new materials. Thus, the student learning process can be modeled by Long Short-

Term Memory network [3] as:

$$\begin{aligned} \mathbf{g}_{k,t} &= \sigma(\mathbf{W}_i \mathbf{a}_{k,t} + \mathbf{U}_i \mathbf{h}_{k,t-1} + \mathbf{b}_i), \\ \mathbf{f}_{k,t} &= \sigma(\mathbf{W}_f \mathbf{a}_{k,t} + \mathbf{U}_f \mathbf{h}_{k,t-1} + \mathbf{b}_f), \\ \mathbf{o}_{k,t} &= \sigma(\mathbf{W}_o \mathbf{a}_{k,t} + \mathbf{U}_o \mathbf{h}_{k,t-1} + \mathbf{b}_o), \\ \mathbf{r}_{k,t} &= \mathbf{f}_{k,t} \otimes \mathbf{r}_{k,t-1} \\ &\quad + \mathbf{g}_{k,t} \otimes \tanh(\mathbf{W}_c \mathbf{a}_{k,t} + \mathbf{U}_c \mathbf{h}_{k,t-1} + \mathbf{b}_c), \\ \mathbf{h}_{k,t} &= \mathbf{o}_{k,t} \otimes \tanh(\mathbf{r}_{k,t}), \end{aligned} \quad (4)$$

where h denotes the dimensionality of hidden state vector. $\mathbf{g}_{k,t}, \mathbf{f}_{k,t}, \mathbf{o}_{k,t}, \mathbf{r}_{k,t}, \mathbf{h}_{k,t} \in \mathbb{R}^h$ are the activation vector of the input gate, forget gate, output gate, the memory cell and the hidden state vector of student k at time t . $\mathbf{W}_i, \mathbf{W}_f, \mathbf{W}_o, \mathbf{W}_c \in \mathbb{R}^{h \times 2d}$ and $\mathbf{U}_i, \mathbf{U}_f, \mathbf{U}_o, \mathbf{U}_c \in \mathbb{R}^{h \times h}$ are weight matrices, $\mathbf{b}_i, \mathbf{b}_f, \mathbf{b}_o, \mathbf{b}_c \in \mathbb{R}^h$ is the bias vector which need to be learned during training. \otimes denotes element-wise product. The $\sigma(\cdot)$ and $\tanh(\cdot)$ denote the Sigmoid and Hyperbolic Tangent function separately.

The correctness of a student's response to an item is dependent on both the current knowledge state of the student and the characteristics of the item. Thus we use the concatenation of student k 's current knowledge state $\mathbf{h}_{k,t}$ outputted by the LSTM and the representation of item $i_{k,t+1}$ that denotes the characteristics of the item, i.e., $\mathbf{v}_{k,t+1}$, to make prediction. The concatenated vector is fed into a fully connected layer to obtain a summary vector $\mathbf{s}_{k,t}$, and then this vector is fed into a Sigmoid activation layer to calculate the probability of correctly answering item $i_{k,t+1}$ by student k . The process can be represented as:

$$\begin{aligned} \mathbf{s}_{k,t} &= \tanh(\mathbf{W}_{fc}(\mathbf{h}_{k,t} \oplus \mathbf{v}_{k,t+1}) + \mathbf{b}_{fc}), \\ p_{k,t+1} &= \sigma(\mathbf{W}_s \mathbf{s}_{k,t} + \mathbf{b}_s), \end{aligned} \quad (5)$$

where $\mathbf{W}_{fc} \in \mathbb{R}^{d_s \times (h+2d)}$, $\mathbf{W}_s \in \mathbb{R}^{d_s}$, $\mathbf{b}_{fc} \in \mathbb{R}^{d_s}$ and $\mathbf{b}_s \in \mathbb{R}^1$ are the weight matrices and biases to be learned, and d_s denotes the dimension of the summary vector. $p_{k,t+1}$ is the probability that student k can answer item $k+1$ correctly.

2.3 Hierarchical Structure Constraint

In fact, there exists a concept-item graph between items and concepts. The concept-item graph provides us with the grouping information of the items. The items related to the same concept can be considered as belonging to the same group. They should be similar with other items within the same group, while dissimilar with items in other groups. At the same time, the concept should capture the characteristics of all items related to it and can approximately represent all these items.

Based on the above analysis, we introduce a hinge loss which tries to maximize the margins among different groups to model the hierarchical structure of items. We apply the embeddings of concepts to represent the general group characteristics of all the items related to the concept. When deriving the representations of items and concepts, we keep the item similar to its corresponding concepts, and on the contrary, make it far away from other concepts. Thus, the hinge loss between an item n and a concept m is defined as

$$l_h^{m,n} = \begin{cases} \max\{0, 1 - \mathbf{e}_{i_n}^T \mathbf{e}_{c_m}\} & q_{m,n} = 1 \\ \max\{0, 1 + \mathbf{e}_{i_n}^T \mathbf{e}_{c_m}\} & q_{m,n} = 0 \end{cases}, \quad (6)$$

where \mathbf{e}_{i_n} and \mathbf{e}_{c_m} are the embeddings of the item i_n and concept c_m , and $q_{m,n}$ is an indicator in the item to concept

mapping matrix Q indicating whether the item n is related to concept m . $q_{m,n} = 1$ indicates that item n is related to concept m , while $q_{m,n} = 0$ means that item n is not related to concept m .

2.4 Loss Function

The objectives of the proposed model are two folds: One is to make accurate predictions of students' responses, and the other is to learn meaningful embeddings of items. Based on these two objectives, in the training stage, we need to minimize the prediction loss and the hinge loss simultaneously.

For student k answering item $i_{k,t}$ at time t , the prediction loss $l_{k,t}$ can be modeled with the binary cross-entropy:

$$l_{k,t} = -(y_{k,t} \log(p_{k,t}) + (1 - y_{k,t}) \log(1 - p_{k,t})), \quad (7)$$

where $p_{k,t}$ is the probability that student k can answer item $i_{k,t}$ correctly and $y_{k,t}$ is the correctness of the response of student k at time t .

The total loss can be represented as the weighted sum of the total prediction loss and the total hinge loss:

$$\mathcal{L} = \sum_{k=1}^{|\mathcal{K}|} \sum_{t=1}^{t_k} l_{k,t} + \alpha \sum_{m=1}^{|\mathcal{C}|} \sum_{n=1}^{|\mathcal{I}|} l_h^{m,n}, \quad (8)$$

where t_k is the total number of questions that a student k attempted, and $|\mathcal{K}|$ is the number of students. $|\mathcal{I}|$ and $|\mathcal{C}|$ are the number of items and concepts in \mathcal{I} and \mathcal{C} respectively. $l_h^{m,n}$ is the hinge loss defined in Eq. 6. α is a hyper-parameter to balance the weight of prediction loss and hinge loss.

3. EXPERIMENTS

In this section, we present the experiments that evaluate the proposed DHKT model on knowledge tracing task. These experiments are performed on three real-world datasets.

3.1 Datasets

The ASSIST09¹ and ASSIST12² datasets were collected from the ASSISTments tutoring system [2]. In the experiment, we use skill builder dataset. In the preprocessing, we remove all duplicated records and the records without a skill id or without a skill name and the records without a $\{0, 1\}$ value of the "correctness" attribute. In addition, we also remove the students with a sequence length less than three. After preprocessing, there are 3,991 students, 227,156 records, 13,876 items and 96 concepts in the ASSIST09 dataset. The ASSIST12 dataset contains 270,66 students, 2,541,201 records, 45,716 items and 245 concepts after preprocessing.

The Statics dataset³ was collected from a college-level engineering statics course [5]. This dataset includes transactions from two different modes: tutor mode and assessment mode. Since the transactions from assessment mode for the same student have the same timestamp, we cannot determine the order of these transactions. Thus, only the transactions from tutor mode are included in the experiment. Also, we remove the students with less than three transactions. After preprocessing, there are 317 students, 137,711 records, 987 items

and 280 concepts. The statistics of the three datasets are shown in Table 1.

3.2 Baselines and Experimental Settings

To evaluate the effectiveness of the DHKT model, we compare the DHKT model with the state-of-the-art knowledge tracing models, including Item Response Theory (IRT) [10], Hierarchical Item Response Theory (HIRT) [10], Performance Factor Analysis (PFA) [8], Bayesian Knowledge Tracing (BKT) [1] and Deep Knowledge Tracing (DKT) [9]. IRT, HIRT, which is a Bayesian extension of IRT by considering the hierarchical structures between concepts and items, and PFA make predictions based on the logit function. BKT models the sequence of responses and makes predictions based on the Hidden Markov Model. DKT applies RNN to model the response sequence and make predictions. To evaluate the effect of incorporating concept-item graph in deep knowledge tracing, the variations of the proposed DHKT model: EDKT, Fine-grained EDKT and DHKT-, are also compared. These variations share the same network structure with DHKT, but they are different in terms of the input and the value of α . EDKT and Fine-grained EDKT use the item embedding and the concept embedding as the input separately and $\alpha = 0$. DHKT- is the reduced model of DHKT where only the item embedding is used as input in Eq. (2). In the ASSIST datasets the skill_id is considered as the concept and the problem_id is considered as the item. In the Statics dataset, the problem_name is the concept and the step_name is the item. The PFA, BKT, DKT and EDKT take concepts as input while IRT, Fine-grained EDKT and DHKT- take items as input. The concept-item graphs are constructed according to the relations between items and concepts and are used by HIRT and DHKT.

We split each of these datasets into training and testing datasets on student level. For each dataset, we randomly select 20% of the students as the testing dataset and keep 80% of the students as the training dataset to learn the parameters. We randomly select 20% of the training students for validation. The training and testing datasets for all the models are the same. For training the DHKT model, batch size is set to 32, and the number of epochs is set to 100. The hidden state dimensionality h is set to 100. The hyper-parameters are tuned on the validation datasets. We tune the embedding dimensionality and the balance parameter α using grid search. The candidate values for embedding dimensionality d are $\{25, 50, 100\}$, and α 's in Eq. (8) are $\{0.001, 0.01, 0.1, 1\}$. The loss function is optimized by Adam algorithm [4], which is a gradient-based optimization algorithm based on adaptive estimates of lower-order moments. We set the learning rate to 0.01. To avoid the exploding gradient problem, gradient norm clipping strategy [7] is

Fine-grained EDKT	0.7342	0.7428	0.8251
DHKT-	0.7780	0.7677	0.8311
DHKT	0.7866	0.7747	0.8333

adopted at the threshold of 20. We use dropout with a probability of 0.6 to alleviate the overfitting issue.

The Area Under ROC Curve (AUC) is used to evaluate the performance of all the models, in which ROC curve plots true positive rate versus false positive rate in a binary classification task. For each model, we run five times with random initialization and report the average AUC. The AUC of the testing dataset is calculated using the model with the highest validation AUC value among 100 epochs.

3.3 Results

The AUC values for different models on all three datasets are shown in Table 2. The proposed DHKT model achieves the highest AUC on all the three datasets. The reduced model DHKT- cannot beat DHKT, but it still outperforms all other baselines on the three datasets. The improvement from Fine-grained EDKT to DHKT- demonstrates the effectiveness of incorporating the concept-item graph. The difference in the performance between DHKT and DHKT- indicates that exploiting general level information is useful in deep knowledge tracing.

3.4 Embedding Visualization

We use t-SNE [6] to visualize the learned embeddings of items by DHKT in a 2-D space to qualitatively assess the interpretability of the representations. For comparison, we also plot the learned item embeddings on the three datasets of the Fine-grained EDKT. The color of the dots represents the concept related to the items.

The learned embeddings are shown in Figure 1. Figure 11(a), 11(b) and 11(c) show the learned item representations of DHKT on ASSIST09, ASSIST12 and Statics, and Figure 11(d), 11(e) and 11(f) show the learned item representations of the Fine-grained EDKT model on corresponding datasets. Compared with the items mixed together learned by Fine-grained EDKT, the item embeddings learned by DHKT are well separated and more consistent with the hierarchical structures on the ASSIST09 and ASSIST12 datasets. On the Statics dataset, although some clusters are mixed with each other, the representations learned by DHKT are much better than that learned by Fine-grained EDKT. In addition, the prediction performance of DHKT is better than that of Fine-grained EDKT on the three datasets, which demonstrates the importance of meaningful item representations for knowledge tracing.

4. CONCLUSIONS AND FUTURE WORK

In this work, we propose a novel deep hierarchical knowledge tracing model by incorporating the hierarchical structure of items. The proposed model not only improves the performance of knowledge tracing task, but also provides

Figure 1: Item representations learned by DHKT and Fine-grained EDKT.

meaningful representations of items. The item representations learned by the proposed model are consistent with the hierarchical structure of the items. The superior prediction performance indicates that the hierarchical structure of items plays an important role in deep knowledge tracing, and meaningful representations can help improve deep knowledge tracing performance.

We plan to investigate how to apply multi-level hierarchical structures in knowledge tracing and how to recommend learning materials and items to students based on their knowledge state in the future.

ABSTRACT

While automated essay evaluation techniques have dramatically reduced instructors' grading burden, they fall short of providing instructors with the rich qualitative insights into students' sense making process that a careful read of essays can afford. In this study, we demonstrate how word embedding techniques can serve as a complement to automated scoring, providing instructors with valuable near-time insight into how their students are conceptualizing targeted lesson concepts. For this study, we use a post-test essay associated with two Web-based Inquiry Science Environment (WISE) units that provides instruction about how the sun causes increases in temperature. We create word2vec models fit to students' c-rater scored essay responses at each score level of a rubric designed to assess students' integrated understanding of targeted concepts. Using cosine similarity, we identify, with statistically reliability, the ideas that students at each score level of the rubric used in relation to the concepts targeted in the essay prompt. Our instructor interview reveals the validity of the results in providing insight into students' ideas, differentiated across understanding levels.

1. INTRODUCTION

In the domain of science, new science education reform efforts, like the Next Generation Science Standards (NGSS), call for students to both coherently understand and communicate complex science ideas[6]. Consequently, essays that assess students' developing knowledge of complex science ideas could increase the validity of assessment in science classrooms[6]. Concomitant with the call for increased use of essay assessments is the need for machine-based techniques to quickly and reliably analyze student essays in order to provide instructors with qualitative insights about how their students are developing and connecting complex science concepts.

Advances in the field of natural language processing (NLP) have given rise to automated essay evaluation (AEE) tech-

niques that help instructors meet the challenges of essay scoring. However, there is still the need to develop effective techniques to assess and support students' comprehension of complex ideas expressed in their essays[9]. In order for instructors to provide targeted support based on their students' developing ideas, they need to have the qualitative insight that comes from reading the essays. Without it, instructors are left in the dark regarding the different ways their students make sense of the targeted concepts being assessed by the essay item. Even though instructors may have access to the exemplars used to train AEE models, the distance between the exemplar responses and that of their students can leave instructors guessing about the true nature and quality of their students' understanding. In this study, we describe the development and evaluation of word2vec models that augment the value of automated scoring by analyzing and comparing the conceptual connections that students in different scoring categories express in their essay.

2. BACKGROUND

Research in the field of teaching and learning has shown students' ability to develop an integrated understanding of complex ideas, such energy transfer and transformation, is influenced by how well their instructors notice and understand their ideas[8]. Therefore, to support students in communicating integrated understanding of complex ideas, it is important to develop machine-based analyses that provide teachers opportunities to see, understand, and respond to student ideas.

2.1 Auto-scored Student Essays

In partnership with Educational Testing Services (ETS), we have previously used the c-rater algorithm to score student essays from various assessment items in Web-based Inquiry Science Environment (WISE) units[2]. The student responses used to train the c-rater model were human-coded using a rubric based on the Knowledge Integration (KI) framework[4]. The KI framework supports students to sort through their ideas to develop an integrated understanding of normative science concepts[3]. Since the rubric used to score the essay assessment items in the units prioritizes the links that students make between normative science ideas, the c-rater generated scores reflect the extent to which students' ideas are normative and linked.

To support instruction based on students' ideas, we create skip-gram models[5] of students' c-rater-scored essay re-

sponses. In doing so, we were able to augment automated essay feedback and, thus, provide instructors with quantitative information regarding the correctness of students' ideas and qualitative information regarding the connectedness of their ideas.

2.2 Science Content Knowledge

The WISE units used in this study were designed to support students in developing an integrated understanding of how energy from the sun is transferred and transformed and how those processes cause an increase in temperature. The assumption is that students at each score level conceptualize and connect these science ideas differently. Since the word2vec models encode the semantic meaning of the words as vectors, we can, for example, analyze the way students scoring at the level of 2 conceptualize "temperature" as compared to how students at a level 5 conceptualize "temperature". Using cosine similarity, we can provide teachers with a list of the words that their students have conceptually connected to the target lesson concept (e.g. temperature).

Given this potential, we conducted this study to address the following research questions:

1. Can we develop a skip-gram model from pre-scored essay responses to reliably extract the differential ways students develop and conceptually connect complex science ideas?
2. Do the skip-gram models generate results that are pedagogically informative (i.e. support teachers to notice, understanding, and respond to their students ideas)?

3. METHODOLOGY

3.1 Offline Model Development (RQ1)

Student essay responses were prepared for skip-gram development using standard Python libraries, pywsd and NLTK were used to perform basic NLP techniques (i.e. abbreviation expansion, case-adjustment, punctuation and symbol exclusion, lemmatization, and stopword modification and removal)[1]. Skip-gram models for student responses at the KI rubric score levels (range 2-5, four total) were developed using the gensim library[7]. Model hyperparameters were adjusted to produce cosine similarity results to the various target words that a content-expert validated as conceptually relevant to the prompt. To extract the meaning of a word as used and understood by the student rather than its conventional meaning, we created the word vectors from the study datasets rather than using pre-trained vectors.

3.2 Classroom Evaluation (RQ2)

To determine the efficacy and utility of our skip-gram models to support teacher noticing of student ideas, we conducted a semi-structured interview of the high-school physics instructor whose students' essay responses generated the model results referenced during the interview.

3.3 Datasets

The dataset used in the offline development and evaluation of the skip-gram models consisted of student text responses to the explanation portion of the following post-test essay assessment item:

Let's think about how global warming happens. On a COLD day, Akbar walks to his car that is parked in the sun and has not been driven for a week. Predict the temperature inside the car:

- Colder than the outside air
- Warmer than the outside air
- Exactly the same as the outside air

Explain your answer:

The students of four sixth grade science teachers from two Bay Area middle schools (N=497) generated their responses to this prompt after engaging the WISE Global Climate Change unit (<https://wise.berkeley.edu/project/24751>). In this unit, students learned how solar radiation from the sun can be absorbed, transformed into heat energy, and trapped by greenhouse gases as infrared radiation, which leads to increased temperature.

Student responses were, on average, 34 words long and were human-coded, from 1 (low) to 5 (high), using a KI rubric. Responses received a score of 1 if they were off-task or irrelevant, and, thus, were excluded from the model development dataset. Responses that included normative but unconnected ideas about the transformation of solar radiation to heat received a score of 3. Responses that connected one or more normative ideas about the transformation of solar radiation to heat received a score of 4 or 5, respectively. The distribution of scores were as follows: Score 2 = 243; Score 3 = 92; Score 4 = 42; Score 5 = 23.

The dataset used in the classroom evaluation of the skip-gram models consisted of student text responses to the same essay prompt used for the offline model development and evaluation (see above). The students of a ninth grade physics instructor from a Bay Area high school generated their responses (N=155) before and after engaging the WISE Solar Ovens unit, which focused on designing, building, and testing a solar oven (<https://wise.berkeley.edu/project/24537>). In this unit, students learned about the same energy cycle described in the sixth grade unit, and then explored how different designs influence that energy cycle and temperature change in a solar oven.

Student responses were, on average, 30 words long and were scored using a c-rater algorithm based on the same KI rubric used for the model development dataset. Similarly, responses received a score of 1 if they were off-task or irrelevant and were excluded from the dataset. The distribution of scores were as follows: Score 2 = 82; Score 3 = 46; Score 4 = 22; Score 5 = 3. Due to sparseness of responses at the score level 5, a skip-gram model was not created for this score level.

4. RESULTS

4.1 Offline Model Development (RQ1)

We chose "heat" and "temperature" as target words for our model evaluation, since the essay used in this study was designed to assess students understanding of how solar radiation and infrared radiation cause an increase in temperature. Our initial cosine similarity results from the four skip-gram models appeared to be consistent with our content expert's

Table 1: The cosine similarity results for the target word "temperature" of the skip-gram models associated with each score level using the development dataset. The vocabulary size of each model is in parentheses.

Temperature							
Score = 2 (105)	cos_sim	Score = 3 (55)	cos_sim	Score = 4 (62)	cos_sim	Score = 5 (58)	cos_sim
become	0.999	get	0.998	inside	0.985	get	0.987
reason	0.999	into	0.994	get	0.985	glass	0.981

warmer	0.993	bounce	0.932	bounce	0.922	pass	0.87

Table 2: The most similar words and associated p-values for the target word "heat" of the skip-gram models associated with each score level using the development dataset. The vocabulary size of each model is in parentheses.

Heat							
Score = 2 (105)	p-value	Score = 3 (55)	p-value	Score = 4 (62)	p-value	Score = 5 (58)	p-value
outside	<1.0E-6	outside	2.42E-04	car	1.13E-04	car	0.009
inside	<1.0E-6	inside	0.012	air	0.007	glass	0.009
temperature	<1.0E-6	air	0.049	glass	0.045	infrared	0.009
cold	<1.0E-6	energy	0.049	radiation	0.045	energy	0.042
air	<1.0E-6	get	0.049	turn	0.045	day	0.042
warm	<1.0E-6	into	0.049			light	0.042
get	3.58E-06	warm	0.049			solar	0.042
sun	0.039	trap	0.049				

expectations regarding the ways that students are different scoring levels would connect ideas related to "temperature" (see Table 1). However, these initial results were not reproducible from one model run to the next, in terms of exact words and relative cosine similarity rank. The top 8 results for each model within a given run displayed patterns consistent with the content expert's expectations, albeit with variable reproducibility.

We used distribution probability to establish the statistical reliability of our model results. Specifically, we used hypergeometric and binomial distribution test, respectively, to determine the probability that any given word in the model's vocabulary would appear in the top 8 cosine similarity results and do so consistently enough to yield a p-value < 0.05. We ran each model 12 consecutive times on a random sample of the essay responses, where the number of responses in the sample equaled the total number of responses in the dataset.

Using the development dataset, we generated a statistically reliable list of the words based on the model results for the target word "heat" (see Table 2). Examination of this list revealed conceptually meaningful differences across the scoring levels, as confirmed by the content expert and physics instructor. These model results indicate a typical progression of student ideas when they are beginning to understand the mechanism of how solar radiation transforms to heat.

4.2 Classroom Evaluation (RQ2)

To investigate the alignment of the model results with the instructor's expectations of the conceptual connections that

Table 3: The most similar words for the target word "temperature" of the skip-gram models associated with each score level using the classroom dataset. The vocabulary size of each model is in parentheses.

Temperature		
Score = 2 (92)	Score = 3 (68)	Score = 4 (62)
become	get	inside
reason	into	get
colder	become	glass
inside	glass	into
time	inside	become
get	particle	travel
hot	may	radiation
warmer	bounce	bounce

students at each score level would make, we presented the instructor with the cosine similarity results from each model for the target word "temperature" (see Table 3). Although the statistical reliability for the model results had not yet been established, we asked the instructor to interpret the results for each individual model and cross-comparatively. The instructor commented that the results from the model resonated with her expectations of what a developed understanding looks like and what a still-developing understanding looks like.

Furthermore, we asked the instructor when and how she might use the information provided by our models. She indicated that she would use a tool like this as a formative assessment to see what her students' ideas were while instruc-

tion was still ongoing. She went on to say that she could use the information from the models to inform her instruction, and that it would help her to decide if she needed to have a whole class conversation, do a demo, or show a video to support her students in sorting and integrating their ideas towards normative understandings.

5. DISCUSSION

5.1 Typical Classroom Datasets

The ability to support teaching and learning by developing unsupervised models using essay response data has historically been stymied by the need to train these models on large datasets (i.e. hundreds of responses)[9]. Since our aim was to provide instructors with specific, rather than generalizable insight into student thinking, we were able to use a small dataset with as few as 23 responses in a scoring category to train our skip-gram models. Our models demonstrate that the data generated from one instructor's teaching load (i.e. 4 class periods of 30-40 students) may be sufficient to provide meaningful insight into student thinking. Therefore, using their small-scale data, instructors with relatively small class sizes (e.g. K-12 teachers, liberal arts instructors, or seminar leaders) can benefit from the insight afforded by word embedding models.

By training the models for specific instructor-student contexts rather than for general use across all instructors, we can give instructors insight into how their group of students are understanding the target lesson concepts. This subpopulation-specific insight affords instructors the ability to tailor their instruction based on the ideas held by their students rather than on the population-level conceptions provided by large-scale research. Armed with such nuanced insight, instructors can feasibly engage in knowledge integration-based instruction in which they attend to and build on students' ideas.

5.2 Capitalizing on Essay Assessments

Education reform efforts that call for students to communicate their understanding of complex ideas have identified essays as valid and effective learning assessments[6]. The results from this study highlight the ability of word embedding models to help instructors capitalize on the affordances that essays have for revealing how students conceptualize and connect complex ideas.

The automatically generated c-rater scores allow the teacher to know which students hold at least one normative idea (score 3) and which can make normative conceptual links (scores 4 and 5). However, this does not provide them with information about what these ideas are or of the other potentially productive, but non-normative ideas their students are holding. The conceptual connections shown by our models give an indication of the ideas, both normative and non-normative, that students are holding as they answer the essay question. Therefore, the output from our models augments the instructional value of autoscored essays by providing instructors with statistically reliable, qualitative insight with which to see, understand, and respond to student ideas. Since the models are developed from essays at each score level, upon viewing the results, an instructor can identify a potential learning progression and how to support their

students in further developing an integrated understanding of the complex ideas.

6. CONCLUSION AND NEXT STEPS

The results from this study provide clear next steps toward supporting teaching and learning. First, we need to determine the most effective means of displaying the model results and develop an interface through which instructors can view the results and explore various conceptual connections. Our partner instructors have expressed that their confidence in computer model results is linked to the extent to which they understand how the model generates the results. Therefore, it is our research priority to develop a model that both generates meaningful results and can be easily explained. Second, the utility of the results in supporting student learning needs to be further validated by evaluating student outcomes based on targeted instructor interventions.

Although the essays used in this study were from the science domain, there is broad application for the technique to other domains, as the only prerequisite is that the text responses be precategorized, either by scoring or other means.

ABSTRACT

Discussion forums are the primary channel for social interaction and knowledge sharing in Massive Open Online Courses (MOOCs). Many researchers have analyzed social connections on MOOC discussion forums. However, to the best of our knowledge, there is little research that distinguishes between the types of connections students make based upon the content of their forum posts. We analyze this effect by distinguishing on- and off-topic posts and comparing their respective social networks. We then analyze how these types of posts and their social connections can be used to predict the students' final course performance. Pursuant to this work we developed a binary classifier to identify on- and off-topic posts and applied our analysis with the hand-coded and predicted labels. We conclude that the post type does affect the relationship between the students and their closest neighbors or community members clustered communities and their closest neighbor to their learning outcomes.

Keywords

MOOC, social network analysis, forum participation

1. INTRODUCTION & BACKGROUND

Social interactions are an essential component of learning. Peer collaborators in courses provide support by engaging in informal advising, sharing "institutional knowledge", and engaging in the co-construction of knowledge [6]. Students who lack strong social connections are more prone to feeling lost or discouraged in a course and are more likely to drop out [12]. This issue is of particular interest in Massive Open Online Courses (MOOCs), which seek to scale classroom instruction to hundreds or even thousands of students supported by a single instructor. Prior researchers

have shown that students in MOOCs do form community structures and that those structures are correlated with their learning [7, 4, 1, 11]. Brown et al. [1], for example, found that students connected to peers with a similar course performance.

While prior research has shown that students form stable social structures in MOOCs, the impact of those connections on students' performance has not always been consistent. Jiang et al. analyzed an algebra MOOC, and found that attributes of the students' social network were correlated with the students' final grades, but they found no relationship between the same variables in a different MOOC on finance [4]. Houston et al. likewise examined the forum activities that were most strongly associated with final grades in three different MOOCs and found that the addition of social centrality and similar features had no impact on their predictive models [3]. This inconsistency may be explained by the fact that the types of discussions students have and their relevance can change from class to class and that prior analyses have focused primarily on the overall social structure and not the content of the discussions. Though the peer communication features in MOOCs are intended to foster content engagement, many of the most active discussion-topics are often social conversations, critiques of the class videos, or exchanges of career advice [8]. Prior researchers have developed automated detectors to classify these posts into on- and off-topic comments and to evaluate the relative proportion of relevant discussions to learning outcomes [5, 10].

Our goal in this study is to examine how the topical content of forum discussions affects students' social relationships, as well as how they connect to their learning outcomes by addressing the following question: *Does the type (on- or off-topic) of conversation affect the relevance of students' social networks to their learning outcomes?*

2. DATA

For our analysis, we used data from a MOOC on "Big Data in Education" provided by The Teachers College at Columbia University and hosted on the Coursera (BDE 2013) and EdX (BDE 2015) platforms in 2013 and 2015 respectively. This

"What You Say is Relevant to How You Make Friends:
Measuring the Effect of Content on Social Connection" In:
*Proceedings of The 12th International Conference on
Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe
Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp.
679 - 682

was offered as an 8 week course that includes material from a graduate-level course on educational data mining and the analysis of big data in education. This curriculum introduces students to basic data collection and data analysis methods such as visualization and clustering. The course offers weekly lectures in the form of videos and individual assignments or quizzes which contribute to students' final grade (grade scale from 0 to 1). The students learn how and when to do educational data mining and learning analytics on data. The course was structured around weekly lecture videos and individual quizzes. The students' final course grade is a composite score based upon these quizzes. In the 2013 class, 1380 students completed at least one quiz, 778 students made at least one post or comment on the discussion forum producing a total of 603 discussion threads consisting of 4259 posts in total. In 2015, 320 students completed at least one quiz, 519 students produced 625 discussion threads with a total of 2056 posts. We manually annotated all of the posts and comments separating them into on- and off-topic entries after removing non-English posts from the dataset. Table 1 includes summary information about the number of students who received 0 or non-0 grades and posted on- or off-topic posts from both offerings of the course. Table 2 shows the number of posts and threads (defined by the starter post) of each type in each course.

	Content	0 grade	non-0 grade	Total
BDE 2013	on-topic	156	377	533
	off-topic	187	220	407
BDE 2015	on-topic	58	83	141
	off-topic	51	44	95

Table 1: Demographic of students grade and content

	Content	Post	Thread
BDE 2013	on-topic	2845	405
	off-topic	1388	380
BDE 2015	on-topic	1050	151
	off-topic	1006	367

Table 2: Number of on- and off-topic posts and threads

Tables 1 and 2 shows that in both courses, the students were more likely to take part in the on-topic discussions than the off-topic ones, especially for those who received non-0 grades. However, in 2015, we observed that though the on- & off-topic post counts are close to each other, the number of threads started with off-topic posts were smaller. This may be due to the fact that the EdX platform includes an optional private chat room for users, logs which we did not have access to.

3. METHODS

Prior researchers have shown that students' final grades are strongly related to those of their closest classmate or 'Best Friend' (BF) in traditional classroom [2]. This relationship also holds in online courses [11] and is also true for students' neighbors in a community structure [1]. In contrast to general assumptions the students are not always connecting with others who need help or people who share a goals or background but with people at their same level of perfor-

mance, in this study, we used exactly the same network generation approach as in our prior work [11] to build the social network graph and to evaluate the relationship between student communities and their final grades. And applied the Girvan-Newman algorithm with the "natural cluster number" approach described in [1] to identify coherent communities. We then applied the Kruskal-Wallis(KW) test to evaluate the correlation between clusters and performance.

In this approach, we treat forum participants as nodes, and we construct arcs between the individuals as weighted edges based upon their individual communications. In this approach we add a directed arc from the author's node to nodes representing the authors of all the comments that precede it in the thread. All of the forum contributors in the thread will be connected to one another. As the average thread length of our two datasets are 6.8 and 3.1 respectively, we developed this approach based upon the assumption that participants read the whole thread before they post any comments. Thus, we consider each reply to be an indication of an implicit social connection between forum participants. Once the raw directed graph has been constructed we modify the graph by eliminating all isolated nodes and merging the parallel edges to get a weighted undirected graph.

4. RESULTS

Table 3 shows the order (number of nodes) and size (number of edges) of the graphs that we obtained for the different content types and student groups (with/without 0 grade students) at the end of week-2. As we have established in prior work, the second week is considered the most important cut-off point for students to stay in or drop out of a course and to form their social networks [11]. We can observe that, in both courses, including the 0 grade students, students preferred to participate more in off-topic conversation than on-topic. According to the number of nodes and edges by the end of week-2, for an on-topic network, the edges still increase in frequency after week 2; however, for the off-topic posts, the social network has already formed at this time point. This suggests that the off-topic discussions may have been confined to a stable set of threads that only grew longer, or were confined to the same stable set of chatty people. Furthermore, for the non-0 students, they were more likely to start conversations for on-topic content, than the 0 students. One potential explanation for this is that students who did not plan to obtain a certificate, and who registered for free, participated in conversations such as introducing themselves to each other at the beginning of the course and then lost interest in the course. Another interpretation is that some of the students worked in spurts at the beginning but dropped out because the course did not fit their schedule over time. Our ongoing analysis of the forum content has shown that a number of the posts are also about early issues, such as course logistics and software. These issues became less relevant as the course progressed. Irrespective of the cause, the social structures are well established for off-topic discussions early enough that instructors should be able to provide advice early enough to the students who have lost interest early on.

Table 4 shows the number of students and the average final grade for each group of students with/without 0 grade. We found that students who participated in both the on-

	Content	Node*	Edge*	Grade	Node	Edge
2013	on-topic	392	2185	with 0	508	3778
				non-0	367	2713
	off-topic	356	9483	with 0	429	10389
				non-0	234	1884
2015	on-topic	182	637	with 0	199	721
				non-0	111	332
	off-topic	370	1044	with 0	392	1112
				non-0	98	95

Node*: Number of nodes at the end of week 2

Edge*: Number of edges at the end of week 2

Table 3: Graph order and size

and off-topic discussions received the highest average grade in the course. Students that only participated in off-topic discussions received the lowest final grade when compared to others. These results indicate that not only is sharing knowledge about course content is important, but participating in non-course content also has an impact on their learning process.

We also examined the growth rates of the number of posts, users and new threads as time progressed. We defined a new thread as being on- or off-topic based upon the head post that initiated it. For BDE 2013, on-topic posts and new threads increased over the whole course period, while off-topic posts appeared primarily at the beginning of the course before declining sharply. As for new users, they came in at the beginning to talk primarily on off-topic content, but new users were more likely to make on-topic conversation afterwards. However, for BDE2015, we observed that all three elements in the on-/off-topic social networks grew monotonically at a similar rate and that the number of new off-topic threads and users was always more than the on-topic ones. One of the potential reasons could be that students discussed course content topics in the private chat-room, rather than in the public forum. As one example, at the end of the BDE2013 course, there were 55,179 registered users, yet the final course social interaction graph contained only 778 participants, including 1 instructor and 2 teaching assistants. Some of the forum participants did not complete any quizzes, or even attempt to obtain the certificate, but still chose to engage in on- and off-topic discussions with others. On the other hand, some of the students who worked hard on the course did not contribute to the forum at all. There were 1,381 students who received a non-0 final grade; 934 of which did not post in the forum at all, while 304 zero final grade students did. It is conceivable students only posted when they faced particular difficulties, or that they sought help elsewhere as participation in the course forum was not a necessary condition for completion.

4.1 Social Interaction Analysis

As part of our analysis we also replicated the Best-Friends comparison as used by Brown et al. Here we identified each student's closest neighbor in the course, excluding members of the teaching staff, and then calculated a direct correlation between their grades and those of their best friends. Since the data was non-normal, we used Spearman's Rank Correlation Coefficient as a non-parametric test for association [9]. Our results are shown in Table 5.

	Content	Grade	BF	Comm
BDE 2013	on-topic	with 0	0.96	<0.05
		non-0	<0.05	<0.05
	off-topic	with 0	0.98	<0.05
		non-0	<0.05	0.08
BDE 2015	on-topic	with 0	0.24	<0.05
		non-0	<0.05	<0.05
	off-topic	with 0	0.06	<0.05
		non-0	0.38	0.30

Comm: KW test for community - grade

Table 5: Social connection correlation with content

Table 5 shows that the relationships between students' grades and those of their best friends were consistent between the traditional courses studied by Fire et al. [2] and MOOCs, but not immediately. Our results show that MOOC students, except those who did not submit any assignments, performed similarly to their closest peers.

5. CONCLUSION & DISCUSSION

In this paper, we distinguished posts and comments into on-topic (course relevant) and off-topic (non-course relevant) before analyzing students' social activities and their final grades. Interestingly, we drew a different conclusion from our previous work. In the BDE2013 dataset, including 0 grade students, we found no correlation between the students' closest 'best friend' and their performance, while the clustered community structures were significant related to their to performance. When we break this down into on- and off-topic networks respectively we found that there was a significant correlation with the community structure and grade for on-topic posts. For the off-topic, by contrast, only a moderate relationship was observed. For the BDE2015 non-0 students, the off-topic connection was not relevant to their performance. This is also shown by the average cluster grades for each group. This supports our original argument that the off-topic discussions may be confusing the social network analyses.

Additionally, Students who showed up in both the on- and off-topic discussions received the highest grade, higher than those that focused on the on-topic discussions alone. Students only made off-topic discussion received the lowest grades overall. Thus although participation in the on-topic discussion facilitated the students' learning, chatting with their peers on random topics was also relevant to their learning, albeit weakly. Additionally, according to Table 3, for all of the students, the off-topic graph was much bigger than the on-topic graph, while for the non-0 grade students, they were more likely to post course content topics than random chat. Thus, we conclude that, for the non-0 grade students who focused their efforts on finishing quizzes, passing the course, and receiving a certificate, participation on the forum helped them improve their grade and keep them from dropping out. By contrast, when we consider all of the students, including those with a 0 grade, the behavior of their closest peers does not seem to have affected them consistently. One possible explanation for this may be that 97% of the students received a 0 grade.

			on-topic	off-topic	only in on-topic	only in off-topic	in both on/off-topic
2013	with 0	students	508	429	299	220	209
		grade	0.51	0.38	0.44	0.16	0.61
	non-0	students	367	234	195	62	17
		grade	0.70	0.69	0.67	0.58	0.74
2015	with 0	students	199	392	100	293	99
		grade	0.33	0.14	0.26	0.05	0.40
	non-0	students	111	98	49	36	62
		grade	0.59	0.54	0.53	0.38	0.64

Table 4: Average grades for students in different social interaction

Moreover, as prior studies have shown the students formed the bulk of the social structures by the end of week 2. We found that 91% of the the off-topic connections had been formed by then. For the on-topic social network by contrast, only 57% of the connections had been formed by week 2. This highlights one of the limitations of prior work that conflated these social structures and it highlights the crucial importance of distinguishing posts by content. We observed different results for the BDE2015 dataset. This class had less proportion of on-topic discussions than BDE2013. This may be due in part to the fact that the edX platform provides support for private a chatrooms which students and instructors may use for side discussions. We were unable to access that data and it may be the case that much of the relevant communications were carried on there.

Discussion forums are widely used in MOOCs to support knowledge co-construction, but the connections between on-line social interaction and learning outcomes is still subject of some debate. As our study has shown the social network structures can be used for information provided we focus on the important on-topic discussions. And, as we have also shown it is possible to use trained models to support this classification, even ones that are trained in part across course offerings. Thus these findings highlight the critical importance of analyzing forum post content when exploring the relationship with learning outcomes; and to draw conclusions carefully when we work with datasets of this type.

In future work we plan to evaluate the impact of automatic classifiers and guidance, both for students and instructors, on students’ course performance, topic comprehension, dropout, and their final grades. This kind of help, we argue, will help students and instructors to manage the course content more effectively and will thus increase student engagement, reduce dropout, and improve other student outcomes.

Deep-IRT: Make Deep Learning Based Knowledge Tracing Explainable Using Item Response Theory

Chun-Kit Yeung

ABSTRACT

Deep learning based knowledge tracing model has been shown to outperform traditional knowledge tracing model without the need for human-engineered features, yet its parameters and representations have long been criticized for not being explainable. In this paper, we propose *Deep-IRT* which is a synthesis of the item response theory (IRT) model and a knowledge tracing model that is based on the deep neural network architecture called dynamic key-value memory network (DKVMN) to make deep learning based knowledge tracing explainable. Specifically, we use the DKVMN model to process the student's learning trajectory and estimate the item difficulty level and the student ability over time. Then, we use the IRT model to estimate the probability that a student will answer an item correctly using the estimated student ability and the item difficulty. Experiments show that the Deep-IRT model retains the performance of the DKVMN model, while it provides a direct psychological interpretation of both students and items.

Keywords

Knowledge tracing, item response theory, deep learning.

1. INTRODUCTION

Generally, the knowledge tracing task can be formalized as follows: given a sequence of student's historical interactions $\mathbf{X}_t = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_t)$ up to time t on a particular learning task, it predicts some aspects of his next interaction \mathbf{x}_{t+1} . Question-and-answer interactions are the most common type in knowledge tracing, and thus \mathbf{x}_t is usually represented as an ordered pair (q_t, a_t) which constitutes a tag for the question q_t being answered at time t and an answer label a_t indicating whether the question has been answered correctly. In many cases, knowledge tracing seeks to predict the probability that a student will answer a question q_{t+1} correctly given the sequence \mathbf{X}_t , i.e., $P(a_{t+1} = 1 | q_{t+1}, \mathbf{X}_t)$.

Many mathematical and computational models have been

developed to solve the knowledge tracing task. These models can be grouped into two categories [3]: (1) a highly structured model whose parameters have a direct meaningful interpretation, e.g., Bayesian knowledge tracing (BKT) [2] and performance factors analysis (PFA) [4]; (2) a highly complex but general-purpose model whose parameters are difficult to interpret, e.g., deep knowledge tracing (DKT) [5] and dynamic key-value memory network (DKVMN) for knowledge tracing [9]. The former category typically provides more insight besides the prediction result, while the latter usually performs better without requiring substantial feature engineering by humans. To the best of our knowledge, there has not yet been a model that is highly complex and general-purpose, yet simultaneously explainable. Therefore, it is appealing to devise a model that inherits the merits of these two categories.

In this paper, we propose *deep item response theory* (Deep-IRT) to make the deep learning based knowledge tracing model explainable. The Deep-IRT model is inspired by the Bayesian deep learning [7] and is a synthesis of a deep learning model and a psychometric model. Specifically, the Deep-IRT model utilizes the DKVMN model [9] to process input data and return psychologically meaningful parameters of the IRT model [6]. The DKVMN model performs feature engineering job to extract latent features from student's historical question-and-answer interactions. Then, the extracted latent features are used to infer the difficulty level of and the student ability on each KC over time. Based on the estimated student ability and the KC difficulty level, the IRT model predicts the probability that the student will answer a KC correctly. By formulating the knowledge tracing task with both the DKVMN model and the IRT model, we are getting the merits from these two models. The Deep-IRT model benefits from the advance of deep learning techniques, e.g., capturing features that are hard to be human-engineered. On the other hand, we empower the explainability by introducing a well-known psychometric model which can be easily understood by many people.

2. DEEP ITEM RESPONSE THEORY

The Deep-IRT architecture at time t is visualized in Figure 1.¹ Firstly, the knowledge state of each latent concept

¹The detail working mechanism of DKVMN can be found in [9]. In summary, at time t , the DKVMN model first receives a KC q_t , then predicts the probability of answering q_t correctly, and eventually updates the memory using the question-and-answer interaction (q_t, a_t) .

Table 2: The average test results of the evaluation measures, as well as their standard deviations, from 5 trials are reported. As the PFA model can be learned by a closed-form solution, the learned parameters and thus its performance are the same in every trail. Therefore, the standard deviation is not reported for the PFA model.

learning tablet application called 4LittleTrees².

3.2 Results

The model performance of the experiment is shown in Table 2. In addition, we also include PFA model [4] in Table 2 as a baseline model for reference.

All in all, the DKVMN and Deep-IRT models have a similar performance. We conduct two-tailed independent t-tests on each dataset and each evaluation measure between the Deep-IRT model and the DKVMN model. We found that the difference between their performance is not significant for majority of the datasets (with p-value > 0.1). Although we cannot claim that their performance is, more or less, the same based on the large p-value, this result, however, might imply that the Deep-IRT model potentially retains the performance of the DKVMN model.

4. GOING DEEPER IN DIFFICULTY LEVEL

To evaluate the KC difficulty estimated from the Deep-IRT model, we compare the difficulty level learned for the FSAL-F1toF3 dataset with four other sources. The reason why we use the proprietary dataset is that we have the individual questions' difficulty level provided by the publisher. Each question is associated with a difficulty level in $\{1, 2, 3\}$ which represents easy, medium and hard, respectively.

The second source of difficulty level is calculated according to the item analysis [1]. The difficulty level of the item analysis is the percentage of students who answer a question correctly in a test environment. Yet, to be consistent with interpretation with other models, we adopt the percentage of students who answer a question *incorrectly*. Furthermore, as our dataset is not collected from a test environment, a student can answer a same question multiple times. Thus, we only adopt the student's first attempt when calculating the difficulty level. Moreover, we only consider the question on which at least 10 distinct students has answered.

The third source of difficulty level is learned by the one-parameter IRT model. We also use the student's first attempt, only, on a question to learn the IRT model for the sake of avoiding multiple attempts on the same question. Moreover, we adopt $\sigma(\theta_i - \beta_j)$ to be the item response function when learning the IRT model.

Lastly, we trained a PFA model to extract the difficulty level

²More information about the 4LittleTrees can be found on <https://www.4littletrees.com/>.

in a knowledge tracing setting, rather than a test environment setting. In other words, we use the entire student's learning trajectory to learn the question's difficulty level.

Since there are more than two thousands questions in this dataset, we only evaluate a set of questions that belong to a subset of skills. This subset contains five skills that constitute around a fifth of the interactions in the FSAL-F1toF3 dataset, and has in total 131 questions. These skills are "Significant Figures", "Approximation and Errors in Measurement", "Index Notation", "Laws of Indices" and "Polynomials". We visualize the difficulty level obtained from different sources in a pairs plot in Figure 2 with the Pearson correlation r stated in the lower triangular part of the pairs plot. The positions in the pairs plot are ordered according to the evaluation setting and the complexity of getting the difficulty level.

The pairs plot reveals that the difficulty level learned from the Deep-IRT model aligns with most of the other sources with a strong correlation, except for the difficulty level provided by the publisher. Moreover, it is observed that the more similar the models' evaluation setting and complexity are, the higher the Pearson correlation is between the models. For example, the Pearson correlation between the difficulty level from the item analysis model and the IRT model is 0.96, while the Pearson correlation between the item analysis model and the Deep-IRT model is 0.56. Furthermore, it is observed that the difficulty level provided by the publisher is moderately correlated to the one obtained from the item analysis model (0.40) and the IRT model (0.39), but weakly correlated to the one obtained from the Deep-IRT model (0.08). Thus, it would be interesting to examine whether the difficulty level inferred from the Deep-IRT model would be more accurate than other traditional models.

5. CONCLUSION

In this paper, we propose the Deep-IRT model which empowers the deep learning based knowledge tracing model with explainability. Experiments show that the Deep-IRT model retains the performance of the deep learning based knowledge tracing model while simultaneously being able to estimate the KC difficulty level and the student ability level over time. Moreover, the difficulty level estimated by the Deep-IRT model aligns with the difficulty level obtained by other traditional methods, e.g., the IRT model and the item analysis. Thus, it potentially provides an alternative way to estimate KC's difficulty level by utilizing the entire learning trajectory, rather than the traditional educational testing environment.

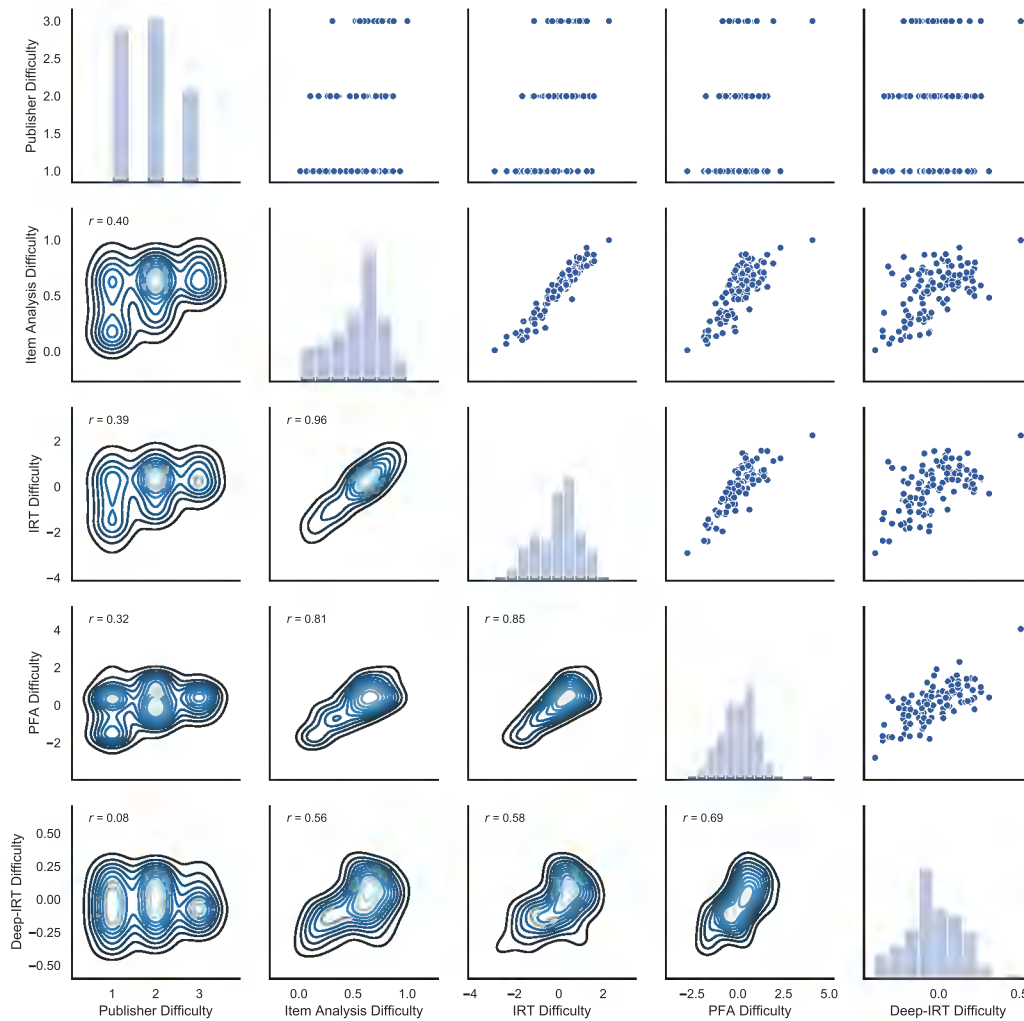

Figure 2: Pairwise comparison of the difficulty level obtained from different sources. The positions in the pairs plot are ordered according to the evaluation setting and the complexity of getting the difficulty level.

ABSTRACT

Adaptive learning systems aim to learn the relationship between curriculum content and students in order to optimise a student's learning process. One form of such a system is content recommendation in which the system attempts to predict the most suitable content to next present to the student. In order to develop such a system, we must learn reliable representations of the curriculum content and the student. We consider this in the context of foreign language learning and present a novel neural network architecture to learn such representations. We also show that by incorporating grammatical error distributions as a feature in our neural architecture, we can substantially improve the quality of our representations. Different types of grammatical errors are automatically detected in essays submitted by students to an online learning platform. We evaluate our model and representations by predicting student scores and grammatical error distributions on unseen language tasks.

1. INTRODUCTION

In general the adaptive learning approach has been shown to lead to improved learning outcomes for student users of educational platforms [4, 8, 10]. However, there remains a question of what is the best methodology to construct representations for students and tasks. Previous approaches manually engineer features to construct representations [7]. These features are usually tuples of a knowledge component (e.g. differentiation, fractions in the case of maths) and student outcome (i.e. whether or not the student demonstrated understanding for that knowledge component through completing the task). A task may contain multiple knowledge components. Whilst this approach is highly interpretable, in the domain of language learning, it is difficult to clearly

divide the tasks into knowledge components. Furthermore, in the recently popular paradigm of deep learning, we have seen that training representations through neural networks have yielded state-of-the-art results in the space of image recognition, and various natural language tasks.

Motivated by this, we propose a methodology of automatically developing high quality representations of students and tasks in a language learning context. Having reliable student and task representations in place facilitates work on downstream tasks such as curriculum learning and recommender systems for language learning.

Representations are derived from a novel neural architecture and real student data collected through the Write & Improve¹ (W&I) assessment and feedback platform for learners of the English language. [13].

Our best-performing model incorporates grammatical error distributions detected by ERRANT [3] as a feature and achieves mean squared error (MSE) of 1.195 on score prediction, an absolute value of 1.093 on a scoring scale of 0-13.

2. WRITE & IMPROVE

On W&I, students are prompted to input a short text of at least 25 words in response to a given question. Once they have completed the task, the W&I automarker assigns each text an integer score s between 0 and 13. The system also automatically provides a grade on the CEFR scale² along with feedback on grammatical errors detected in the text. Table 1 outlines how integer scores are mapped to the CEFR scale. Currently all users of W&I move through the curricu-

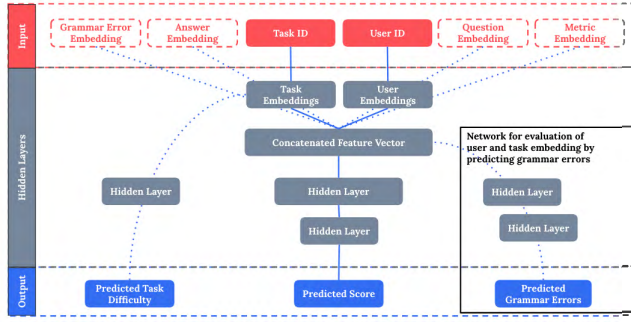

Figure 1: Task score prediction system architecture. Dotted lines and boxes are optional features and network connections.

lum in an unguided and independent fashion. An intelligent tutoring system would instead guide students from task to task in order to personalise their learning experience and improve their level of performance. In order to do that we must learn reliable student and task representations.

We obtained application logs of user activity from the past two years – a total of 3+ million essay submissions by 300k account holders. We filtered the data for users who had submitted at least 10 submissions. We also had a record of the questions (‘prompts’) users responded to and the scores assigned to their texts by W&I’s auto-marker.

3. LEARNING STUDENT AND TASK REPRESENTATIONS

Our primary goal was to predict student scores on a given language learning task based on our representations of students and tasks in W&I. Secondary to that, we check the quality of our student representations by predicting the grammar error distribution of a given student-task tuple. In what follows we describe the data, evaluation metrics and models used in this work.

3.1 Model Architecture

The architecture of our neural system can be seen in Figure 1. The neural network takes as an input a user id u and task id t which are taken as indices in the user embedding layer U and task embedding layer T respectively. $u \in N_u$ where N_u is the number of unique users in the W&I dataset. $t \in N_t$ where N_t is the number of unique tasks in the W&I dataset.

We optimise our system and learn a user embedding matrix U and task embedding matrix T by minimising the mean squared error (MSE) of our predicted score s and the target score \hat{s} .

We introduce an auxiliary objective to predict the difficulty β of each task t , referenced as t_β . The ground-truth labels for task difficulty (beginner, intermediate, advanced) are obtained from the meta-data of each task in the W&I dataset.

3.2 Feature Set

In addition to the score s , the W&I dataset contains prompts and answers in natural language as well as metrics on whether

submission k is the highest scoring submission by user u . We incorporate these additional features into the architecture of the model in order to evaluate their impact on the quality of user and task embeddings.

3.2.1 Answer and Question Embedding

We obtain a vectorised form of each student response and question using 300-dimension word2vec embeddings³ pre-trained on the Google News corpus [5]. Our embeddings are an additive compositional model where the final embedding is a sum of every word in the question or answer. Whilst this model is not state-of-the-art for distributional semantics, Mitchell & Lapata [6] show that the additive model can yield results comparable to more sophisticated models.

3.2.2 Metric embedding

The metric embedding is a 2-dimensional vector. The first dimension is a binary value for whether the score for the submission was the highest score on task t for user u . The second dimension is a binary value for whether the score for the submission was the highest score across all W&I tasks for user u .

3.2.3 Grammar error embedding

A student’s grammatical proficiency plays a vital role in determining how well they perform on a particular task. As we do not know of any system that identifies appropriate use of grammar, we focused on understanding what grammatical structures the student struggles with. This was done by running ERRANT [3], an automated error detection and correction system, in order to identify grammatical errors in the student’s essay.

For each submission k , we constructed a 47-dimensional vector, one dimension for each of the error types observed in the W&I dataset. Each dimension stored the number of times that error type appeared in the student’s essay submission.

$$\langle e_k \rangle = \langle f_k^1, f_k^2, \dots, f_k^{47} \rangle \quad (1)$$

– where e_k is the grammar error embedding e for submission k , and f_k^n is the frequency of errors for error type n in submission k .

3.3 Mean score baseline

Our baseline system for predicting s for user u on task t is to calculate the mean of observed scores by all users for that task. We refer to this baseline as MEAN_SCORE.

3.4 Evaluation

We identify two approaches to evaluating our system and the quality of our learned user and task representations: 1) score prediction; and 2) grammar error prediction.

³A word2vec embedding is a $1 \times x$ dimensional dense vector that represents a word semantically.

Table 2: Score prediction (MSE) and grammar embedding prediction (cosine) results for the top 8 best performing feature combinations (error: grammar error embedding; ques: question embedding; ans: answer embedding; metric: metric embedding).

Model	MSE	Cosine
MEAN_SCORE (baseline)	1.913	-
error+ques+ans+metric	2.254	-0.385
ques+metric	1.942	-0.402
ans+metric	1.951	-0.414
error+metric	1.350	-0.426
ques	2.028	-0.403
ans	2.014	-0.412
error	1.761	-0.410
metric	1.907	-0.393

3.4.1 Evaluation of score predictions

To evaluate the performance of score prediction we use mean squared error (MSE) in common with other works in this field, using global computation where all data points are treated equally [9].

3.4.2 Evaluation of grammar embedding predictions

In order to further evaluate the quality of the learned user and task representations, we also introduce an additional evaluation task of predicting the distribution of grammar errors for a user u on a task t .

This was done by building a network that takes as an input the user \vec{u} and task \vec{t} from the pre-trained embedding U and T and predicts the grammar embedding \vec{g} . Our dataset for grammar error prediction was created by extracting the last submission k of every user u . This was to ensure that the system is predicting the distribution of errors for the users at their most recent knowledge state.

We optimise our system by minimising the cosine proximity of the predicted grammar vector \vec{g} and the target grammar vector $\hat{\vec{g}}$.

4. RESULTS

Table 2 summarises the results of our system. We compare the effectiveness of various features in the prediction of a user's score s on a task t which is evaluated by MSE. We include the top 8 MSE values on the score prediction system and their corresponding cosine value from the grammar error prediction model.

We find that incorporating question and answer embeddings do not provide any performance improvement in terms of MSE beyond the baseline model. The metric embedding provides marginally better results than the baseline with an MSE of 1.907. The grammatical error embedding provides substantial improvements beyond both the baseline and the metric embedding with an error of 1.761. The best performing system incorporates both grammatical error embedding and metric embedding, reducing the MSE to 1.350.

Table 3: Performance across various student and task representations sizes (N_h)

Model	N_h	MSE	Cosine
error+metric	3	1.350	-0.426
error+metric	5	1.297	-0.431
error+metric	16	1.245	-0.415
error+metric	32	1.195	-0.433

Figure 2: t-SNE of 300 randomly sampled student representations classified by different levels of proficiency

Table 3 shows the model that provides the lowest cosine proximity to the target grammatical error vector (i.e. best system) was error+metric, which is consistent with the lowest MSE for the score prediction system.

In order to interpret the relevance of cosine proximity we conducted a Pearson's correlation test between the MSE values from the score prediction system and the cosine proximity scores from the grammar error prediction system. The results show a 0.7883 Pearson's correlation with a p -value of 0.0201 which is statistically significant at $\alpha < 0.05$.

Figure 2 shows a t-SNE [12] of 300 randomly sampled student representations learned by our best performing score prediction system. The students are classified by their proficiency which has been determined by observing the most frequent task level attempted in their five most recent submissions. Qualitatively, the results from the plot are promising as the advanced and intermediate users, whilst present throughout the plot, are more concentrated towards the top right (higher level of language proficiency). Beginner students, on the other hand, are more concentrated in the bottom left. This suggests that the embeddings constructed from our model provide context on the language abilities of the student.

5. DISCUSSION

The results in Table 2 show that incorporating grammar error embeddings provides a reliable signal to learn well-

Student Knowledge Diagnosis on Response Data via the Model of Sparse Factor Learning

ABSTRACT

Cognitive diagnosis aims to analyze the status of knowledge mastery of student and is thus very important for personalized education. The existing methods mostly depend on the empirical Q-matrix from domain experts. However, the knowledge points in Q-matrix are unavoidably overlapping, leading to the weak performance on the practical applications. In this paper, we propose a novel model for student knowledge diagnosis, called Sparse Factor Learning (SFL). SFL learns a meta-knowledge dictionary from student response data of test questions, where the knowledge structure of any entity (e.g., student, question or others) is a sparse linear combination of dictionary atoms. Our method has three innovations for cognitive diagnosis: learning latent nonoverlapping meta-knowledge, sparsely representing the entities, and removing the bias noise for guessing and slipping. To verify our method, we collected the response data from the final exam of C language program of international class and then conducted the experiments for knowledge diagnosis, student grouping and response prediction. The experiment results show that SFL works effectively and results in decent performance. Besides, it delivers that student who favors mathematics and physics can achieve higher score. All codes and data set can be available on our website.¹

Personalized education, Sparse factor learning, Cognitive diagnosis Student modeling, Student grouping

1. INTRODUCTION

In recent years, educational data mining (EDM) is an emerging research field which seeks to develop methods for exploring response data of learners. Researchers in this field aim to discover the true knowledge structure of learners to offer learners accurate assistance. Cognitive diagnosis, a hotspot

issue in EDM research, explains the mental processes that are triggered when test items are solved [2, 5].

Recent progress has been made on applying machine learning algorithms to mine true and latent knowledge structure of learners. These existing cognitive diagnosis methods propose a probability model reflecting learner response data. In contrast to rule-based approaches, machine learning-based models promise to be rapid and inexpensive to deploy. However, latest research proposes “abstract concepts” [1] which are unavoidably overlapping, leading to the intricate results. In addition, it cannot analyze unseen data. Therefore, accurate teaching problem still remains an open issue.

In this paper, motivated by recent progress, we present SFL, a new model to best distinguish learner using their nonoverlapping knowledge structure. This model defined as knowledge learning is designed as sparse representation for student response, which is analogous to dictionary learning [6]. We first observe the data $y_{ij} = 1$ or 0 depending on whether learner j answers question i correctly or incorrectly. SFL model learns the latent nonoverlapping meta-knowledge spaces of certain course and can also represent the real knowledge structure of learners by optimizing a novel objective function. Furthermore, the sparse representation of learners in the meta-knowledge dictionary can be obtained. After that, we cluster learners who have the same meta-knowledges according to this sparse representation and predict whether a learner can response the question correctly. More specifically, our contributions are listed as follows:

- We tackle the weakness of traditional educational models which focus on Q-matrix given by experts. However, the acquisition of the Q-matrix is not easy anytime. Our model still discover essential knowledge structure without Q-matrix.
- We propose a data-driven method called SFL to explore the correlation between inseparable meta-knowledge and learner from student response data. SFL removes the bias noise for guessing and slipping. This model provides natural explanatory power in learning process.
- We apply SFL model to real-world teaching work. We collect more complete data from Northwestern Polytechnical University and draw more meaningful educational conclusion from data.

The rest of paper is organized as follows. In Section 2, we formally put forward to our targeted issue and mathematical model. Section 3 details the algorithm of our SFL model. Simulation and real data experimental results are presented in Section 4. Finally, conclusions are given in Section 5.

2. METHODOLOGY

In this section, we formalize our problem in detail, and propose new method termed Sparse Factor Learning.

2.1 Model for Learner Response Data

In this section, we set forth the definition of meta-knowledge. Meta-knowledge is virtual and *inseparable* atom that learner cannot master. It is believed that all questions and learner knowledge structure consist of these meta-knowledges.

In this problem, we have N learners that answer Q questions. As shown in Figure 1, we are provided with the data \mathbf{Y} from the response of learners over a collection of questions, where $y_{ij} = 1$ or 0 indicating correct or not of the learner j at the question i , respectively. In Figure 2, the matrix \mathbf{D} denotes the relationship between the collection of questions and meta-knowledges where the coefficient d_{ij} indicates the associate degree of the i -th question over the j -th meta-knowledge point. By the way, we denote the correlation between meta-knowledges and learners by matrix \mathbf{X} . Usually, the data is often polluted by subjective response. We therefore consider this educational case by assuming that the i -th learner has guessing and slipping rate on the j -th question by w_{ij} . Thus, we represent observed data over the dictionary in terms of $\mathbf{D}\mathbf{X} + \mathbf{W}$. Our problem could be defined as follow:

Problem Definition 1: Given the learner response data, i.e. binary matrix $\mathbf{Y} = [\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_n] \in R^{Q \times N}$, the primary purpose of our sparse factor learning framework is : (1) learning the overcomplete basis $\mathbf{D} = [\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_k] \in R^{Q \times K}$, where we assign $K \gg Q$ to obtain association between knowledge latent attributes and questions; 2) obtaining the sparse representation matrix $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n] \in R^{K \times N}$ which reflects the connection between meta-knowledges and learners; (3) estimating the bias matrix \mathbf{W} which is a sparse bias matrix.

2.2 The Proposed model

Since real data is binary data, SFL model can be formulation as the following equation shows:

$$\mathbf{Y} = \text{sign}(\mathbf{D}\mathbf{X} + \mathbf{W}) \quad (1)$$

where $y_{ij} \in \{0, 1\}$ is the result of learner j at question i . Utilizing the model (1) and the given observations of question-learner responses \mathbf{Y} , our goal is to estimate the factors $\mathbf{D}, \mathbf{X}, \mathbf{W}$. To solve problem, we exploit these observations as prior information: (1) Meta-knowledges are generally large and overcomplete. (2) Questions are linear combination with meta-knowledges. (3) Each column of matrix \mathbf{X} is sparse and matrix \mathbf{W} is sparse.

3. ALGORITHM

Under the prior information, we propose a new method dubbed Sparse Factor Learning (SFL) and solve this problem using ADMM framework[3].

			d_{ij}	
	0.003	0.021	0.056	0.006

Figure 2: question i involves meta-knowledge j

3.1 Problem Formulation

To estimate \mathbf{D}, \mathbf{X} , and \mathbf{W} , we minimize the objective function as follow:

$$\begin{aligned} \min_{\mathbf{D}, \mathbf{X}, \mathbf{W}} \sum_{i,j} \left\| y_{ij} - \text{sign}(\mathbf{d}_i^T \mathbf{x}_j + w_{ij}) \right\|_F^2 \\ \text{subject to } \|\mathbf{d}_i\|_2 \leq 1, \|\mathbf{x}_j\|_0 \leq s, \|\mathbf{W}\|_0 \leq k \end{aligned} \quad (2)$$

Complied with prior information (3), we impose sparsity on each vector \mathbf{x}_j . We constrain $\|\mathbf{x}_j\|_0 \leq s$ to limit maximum number of nonzero coefficients. Unfortunately, these constraints lead to an NP problem. Hence, (2) cannot be solved efficiently in practice. In order to arrive at an optimization problem that can be solved with a reasonable computational complexity, we relax the sparsity constraint $\|\mathbf{x}_j\|_0 \leq s$ in (2) to L_1 -norm constraint as in [1]. Because the function $\text{sign}(x)$ is not a continuous derivable function, we then use $\text{sigmoid}(x)$.

$$\text{sign}(x) \approx \text{sigmoid}(x) = \frac{1}{1 + e^{-x}} \quad (3)$$

By introducing Lagrange multipliers, our objective function can be reduced into:

$$\min_{\mathbf{D}, \mathbf{X}, \mathbf{W}} \left\| \mathbf{Y} - \text{sigmoid}(\mathbf{D}\mathbf{X} + \mathbf{W}) \right\|_F^2 + \lambda \sum_{j=1}^M \|\mathbf{x}_j\|_1 + \beta \|\mathbf{W}\|_1 \quad (4)$$

where regularization terms $\sum_{j=1}^M \|\mathbf{x}_j\|_1$ and $\|\mathbf{W}\|_1$ induce sparsity on each vector \mathbf{x}_j and matrix \mathbf{W} , and parameters $\lambda > 0$ and $\beta > 0$ are to control the sparsity level.

3.2 The Sparse Factor Learning Algorithm

Inspired by most of dictionary learning algorithm which fix one variable updating another variable, SFL adopts an alternating optimization approach named alternating direction method of multipliers (ADMM) to solve (4). We introduce an auxiliary variable \mathbf{J} in order to make the objection

function of (4) separable. The optimization problem can be rewritten as follows:

$$\begin{aligned} \min_{\mathbf{D}, \mathbf{X}, \mathbf{W}} \quad & \|\mathbf{Y} - \text{sigmoid}(\mathbf{DX} + \mathbf{W})\|_F^2 + \lambda \sum_{j=1}^M \|\mathbf{x}_j\|_1 + \beta \|\mathbf{W}\|_1 \\ \text{s.t.} \quad & \mathbf{W} = \mathbf{J} \end{aligned} \quad (5)$$

The augmented Lagrangian function of problem (5) is

$$\begin{aligned} \mathcal{L}(\mathbf{D}, \mathbf{X}, \mathbf{W}, \mathbf{J}, \mathbf{M}) = & \|\mathbf{Y} - \text{sigmoid}(\mathbf{DX} + \mathbf{W})\|_F^2 + \lambda \sum_{j=1}^M \|\mathbf{x}_j\|_1 \\ & + \beta \|\mathbf{J}\|_1 + \langle \mathbf{M}, \mathbf{W} - \mathbf{J} \rangle + \frac{\mu}{2} \|\mathbf{W} - \mathbf{J}\|_F^2 \end{aligned} \quad (6)$$

where M is Lagrange multiplier and $\mu > 0$ is a penalty parameter. The variables are updated alternately by minimizing its corresponding problem with fixing other variables. The iteration stops when the convergence conditions are arrived. The detailed procedure of solving the proposed SFL problem is described in Algorithm 1.

Algorithm 1 Sparse Factor Learning

Input: Data Matrix \mathbf{Y}

Parameter: $\mathbf{D} = \mathbf{0}, \mathbf{X} = \mathbf{D}^{-1}\mathbf{Y}, \mathbf{W} = \mathbf{0}, \lambda = 0.03, \beta = 0.4$

Output: $\mathbf{D}_{k+1}, \mathbf{X}_{k+1}, \mathbf{W}_{k+1}$

- 1: while not converged ($k = 1, 0, \dots$) do
- 2: fix the others and update \mathbf{J}

$$\mathbf{J}_{k+1} = \max\{\mathbf{S}_{\frac{\beta}{\mu}}(\mathbf{W}_k + \frac{1}{\mu}\mathbf{M}_k)$$

fix the others and update \mathbf{W} :

$$\mathbf{W}_{k+1} = \mathbf{W}_k - \alpha \frac{\partial \mathcal{L}(\mathbf{W}_k)}{\partial \mathbf{W}_k}$$

- 3: fix the others and update \mathbf{X} [4]by:

$$\mathbf{x}_j = \text{BIHT}(\mathbf{y}_j, \mathbf{D}) = \mathbf{H}_M(\mathbf{x}_k + \mathbf{D}^T(\mathbf{y}_j - \text{sigmoid}(\mathbf{D}\mathbf{x}_k + \mathbf{W})))$$

- 4: fix the others and update \mathbf{D} by:

$$\mathbf{d}_{k+1} = \mathbf{d}_k - \beta \frac{\partial F(\mathbf{d}_k)}{\partial \mathbf{d}_k}$$

- 5: update the multipliers:

$$\mathbf{M}_{k+1} = \mathbf{M}_k + \mu_k(\mathbf{W}_{k+1} - \mathbf{J}_{k+1})$$

μ can be a constant value.

- 6: check convergence

$$\frac{\|\mathbf{Y} - \text{sigmoid}(\mathbf{DX} + \mathbf{W})\|_F^2}{\|\mathbf{Y}\|_F^2} < \varepsilon$$

- 7: End while.

4. EXPERIMENTS

In this section, we validate SFL on real-world educational data sets. We conduct the two practical experiments: student grouping and response prediction. Meanwhile, we compare SFL with SPARFA method which is a pioneer work. All experiment codes are implemented by MATLAB R2018a.

NPU-C Dataset: Student data used to test our model is collected from Northwestern Polytechnical University across students in international class who entered the C Language Program final exam in December 2018. First, we collected the response of students of 20 objective questions and the answers to these questions are only right or wrong. The dataset contains two elements: 0 for incorrect answer and 1 for correct answer which is collected by thirty-nine students at twenty questions. Second, to collect the background information, we made a questionnaire with twenty questions containing gender, age, English and Math grade of College Entrance Examination, their favorite subjects, and so on. Here, there is no missing data in the response matrix. More details can be found in our website.

4.1 Student Grouping on Our Data

After obtaining the sparse representation of all students, we utilize k-means and spectral clustering to group the student who has same knowledge structure. We use Jaccard distance as metric and measure our results employing Dun Validity Index (DVI) and Compactness Index (CP), defined as follow:

$$\text{DVI} = \frac{\min_{0 < m \neq n < k} \left\{ \min_{\forall x_i \in \Omega_m, \forall x_j \in \Omega_n} \|x_i - x_j\| \right\}}{\max_{0 < m \leq k} \left\{ \max_{\forall x_i, \forall x_j \in \Omega_m} \|x_i - x_j\| \right\}} \quad (7)$$

The numerator computes the minimum distance between each pair of clusters, while the denominator calculates the maximum distance between all pair of two elements in a cluster. That is, the bigger DVI value corresponds the better cluster.

$$\text{CP} = \frac{1}{k} \sum_{i=1}^k \left(\frac{1}{|\Omega_i|} \sum_{x_i \in \Omega_i} \|x_i - w_i\| \right) \quad (8)$$

where k means the number of cluster and w_i represents the central point corresponding to a certain cluster. The term in bracket is to compute the distance between each point and its central point. Thus, the smaller CP value delivers the better cluster.

We vary the different number of clusters $\{2, 3, 4, 5\}$ and record our results in Table 1 and 2. From Table 1 and 2, we can conclude that our model obtains better clustering performance than using original data directly and the SPARFA. Besides, we choose to use k-means and spectral clustering methods to gather the response data into three clusters. We use DVI evaluation to measure the results and list our results in Table 3 and 4. Table 3 and 4 illustrate that using original data or SPARFA method is not good comparing to SFL method. In addition to these cluster indicators, we draw conclusions from our data (see more in our website): (1) The first group indicates that students who is good at Mathematics and more like Mathematics and Physics will achieve better grades than others in general. (2) The second group shows that students of being weak on Mathematics and Physics seem to be weak on C Language Programming. (3) The third cluster contains many complex reasons depending on their learning. We observed that exercise and study hard after class have a great effect on the final grades.

Table 1: Cluster results using DVI metrics

	2	3	4	5
Original	0.427	0.302	0.333	0.316
SPARFA	0.119	0.119	0.132	0.135
SFL	0.545	0.536	0.535	0.536

Table 4: Comparisons using different cluster method with DVI.

	Original	SPARFA	SFL
K-means	0.462	0.382	1.991
Spectral	0.302	0.119	0.494

4.2 Student Response Prediction

For predicting the responses of a student at questions, we here determine the responses on two factors: the knowledge structure of student composed of few meta-knowledge points and the meta-knowledge involved in questions.

In this experiment, we vary different data sets of different size from $\{5, 10, 15, 25, 35, 39\}$. For each data set, we hold out one of the learner responses as testing set, and train SFL on the rest to acquire the question-metaknowledge matrix \mathbf{D} and the metaknowledge-learner matrix \mathbf{X}_{train} to obtain the above two factors. Because the size of our data is small, we hence use leave-one-out (LOO) validation to achieve more effective evaluations. To obtain more stable result, we run 20 times to achieve the average values shown in Figure 3. In addition, we use the neighborhood classifier for prediction on original data and the SPARFA method to predict student response. We observe that the performance of all of algorithms generally improves as the data size increases. Moreover, the error rate of using original data is not reduced much, and Figure 3 suggests that the error rate of SPARFA method is not reduced much when dataset is small. Generally, the average result of our method performs better. This indicates that our model is more effective.

5. CONCLUSION

In this paper, we remedy the shortcomings of traditional cognitive diagnosis model by proposing a data-based method, called Sparse Factor Learning (SFL) model. SFL has three innovations. First, we exploit the natural concept named meta-knowledge and test paper, questions and knowledge points

Figure 3: Student Response Prediction.

from field experts can be thought as a linear combination with the meta-knowledges. In addition, using the meta-knowledges dictionary, we can have a clear representation of student response data. Second, it is believed that learner can master limited meta-knowledges from one course, and hence we have a sparsity constraint on learner-knowledge matrix. Third, we remove the bias noise of guessing and slipping. Experiments on our practical data show that SFL is effective and has good generalization ability for prediction. In future, we will test our method using more data and design a reasonable strategy for missing data.

ABSTRACT

The analysis of the collaborative learning process is one of the growing fields of education research. In this paper, we present a new method to automatically evaluate the collaboration level of students in groups using computer vision techniques. Instead of single-time solicitation techniques such as self-reported questionnaires to evaluate the collaboration, we evaluate the entire process of the collaboration by analyzing image data captured from groups. We use object detection techniques such as Mask R-CNN method to process our data. This process is based on detecting people and other objects from pictures and video clips of the collaborative learning process, then evaluating the performance of students in the interactive learning and textbook settings using these collaborative indicators. Two collaborative indicators are related to the team's proximity and time on task. We tested our approach to evaluate the group-work collaboration in a controlled study of 33 teams while performing an anatomy muscle painting intervention. The results indicate that our approach successfully recognizes the differences of collaborations among teams of treatment and control conditions, $F_{(1,33)} = 11.42, p < 0.005$. This work may offer implications for automated quality prediction of collaborations among human-human interactions in group-work scenarios.

1. INTRODUCTION

Collaborative learning is a widely-used education pattern featured by small group interaction and team-based evaluation metrics. Typically two or more participants are assigned in the same group and work for a common purpose, which encourages them to learn via teamwork [6]. Researches in the past few years have shown that compared with individual learning or lecture-based learning, collaborative learning as an active learning approach can increase stu-

dents' learning motivation and improve knowledge retention. However, it is undeniable that these benefits only work on the well-formed teams with respectful members which have efficient collaborative activities during the learning process.

In early attempts to analysis collaboration, researchers either established effective collaborative learning models or built reasonable standards for judging the collaborative learning process based on self-reported survey data or collaboration system data. However, those data were collected from class attendance, quizzes scores, and reports which could not directly reflect participants' interaction during the learning activities. The ideal data should reflect the students' actions and emotions during the process, which could be recorded via images or videos. Also considering the learning-based methods, tremendous data can make the model general. On the other hand, there is no objective measurement to automatically evaluate the process of collaboration while students performing group work. One possible evaluation method is defining new criteria using the features extracted from the image or video records.

For image and video data analysis of group-work quality identification, we introduce a new object detection approach to extract useful features such as identifying participants, and objects in the scene. In this study, our goal is using object detection to detect participants and their locations from the image data and then recognize collaborative actions from these proximity features. We use a pre-trained Mask R-CNN (Region-based Convolutional Neural Network, [5]) with the COCO dataset [7] as our object detection approach. We evaluated the usefulness of the Mask R-CNN object detection method in identifying collaborations in a tangible, muscle painting activity.

2. CASE STUDY

We conducted a between-subjects study while performing anatomy learning intervention (muscle painting) in a large laboratory course of General Biology in spring 2018 at Johns Hopkins University. Students worked in pre-assigned teams to complete the muscle painting activity. During the muscle painting activity, pairs of students collaborate to paint twelve muscles of their body using painting supplies. The first student plays the role of a model, while her teammate, as a painter, locates the major upper-limb muscles using the human anatomy diagram in the lab manual [8], and then paints her upper limb. Afterwards, students switch roles, and the upper limb painter becomes a model for the lower

Zhang Guo and Roghayeh Barmaki "Collaboration Analysis Using Object Detection" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 695 - 698

limb. The painting activity was upgraded for the treatment group by using mobile tablet devices instead of the textbook for visualizing the musculoskeletal system. Figure 1 shows two settings of the case study during the muscle painting activity.

Figure 1: Case study setup for participants in pairs to complete the painting activity using either (a) textbook, or (b) tablet.

There was a workstation for each laboratory room to capture videos and photos so that students' team performance can be recorded during the painting activities.

The study was approved by the Institutional Review Board (Protocol HIRB00005021), and oral informed consent was obtained from each participant before the case study commenced. After consent, students entered the painting activity room with their teammates and completed the painting task. All students completed pre and post questionnaires before and after the intervention.

3. DATASETS

Image data. Image data is the pictures and video clips captured from the muscle painting scene every ten-seconds (Figure 3(a) shows one of the snapshots from the scene). Only group members and the tools they used for painting activity were captured in the image data.

Approximately 2000 images was captured in total from 33 teams. Based on different time spent on the painting activities, data for each team had about 25 to 200 images. Each image file was also timestamped for further time on task analysis.

COCO dataset. COCO dataset is a large online open-source dataset and contains photos of 80 easily recognized common objects categories with instance-level segmentation mask, including person, bottle, book, and cellphone [7].

Survey data. Survey data was collected online, generated by the Qualtrics application, towards all participants before and after completing the painting activities. There were two questionnaires in this study. Pre-questionnaire consisted of demographic questions and a pre-test. Post-questionnaire was composed of questions about participants' user experience during collaboration study, including the preference of being a painter or a model, the level of engagement in the activity, and a post-test. This data set will be used in our future work.

4. ANALYSIS OF COLLABORATION

4.1 Object Detection

Object detection is a computer technology related to computer vision and image processing that deals with identifying the instance of semantic objects of a certain class in digital images and videos [10]. It can do both localization and classification. One object detection strategy is to localize each object with a bounding box and do classification on each bounding box area [9]. Thus, object detection methods can help instructors detect participants and extract useful features for analysis from the raw images.

Mask R-CNN approach. Mask R-CNN approach uses the Region Proposal Network (RPN) stage to generate bounding box for each candidate object and uses a more accurate module RoIAlign to extract features from each box and show the bounding-box regression and classification [5] (see Figure 2). By feeding the input image, a CNN feature extractor is able to extract image features which are called feature maps. Then a CNN RPN will create Region of Interests (RoI) which are the candidate object regions generated by RPN and ranked based on their score (how likely is the candidate object region could contain an object). Then the $N = 300$ regions with the highest scores are kept. Each of them will be warped into fixed dimension by RoIAlign and feed into three parallel branches: two Fully Connected (FC) layers as Faster R-CNN make classification and boundary box prediction and two additional convolution layers to build the binary masks. The top 100 detection boxes are kept and form a $100 \times 80 \times 28 \times 28$ tensor, where 80 represents the number of classes in the COCO training dataset, and 28×28 represents the size of each predicted mask. The resized masks and the bounding boxes can be overlaid on the original input image as a transparent layer.

Using a pre-trained neural network by COCO dataset [1], we are able to apply Mask R-CNN to automatically detect participants, and their locations from the collaborative learning activities image data as shown in Figure 2. In our implementation, we focused on the following features of the object detection results (Figure 3(b)): image file name, category name, bounding box coordinates and the confidence score for each object. These features are the key points for collaborative learning analyses in our muscle painting scenario. We detected the participants with person confidence score ≥ 0.9 .

4.2 Collaboration Metrics

To evaluate students' performance during our collaborative learning process, we defined two indicators: Level of collaboration, and Time on Task. Level of collaboration is formulated by Overlapping area and ratio.

Level of Collaboration. In muscle painting activity, collaboration was crucial in terms of how closely the participants work together. Especially close physical distance or proximity, and the amount of time students work together to perform the task was part of the learning process. We measured this factor using Mask R-CNN approach and named it level of collaboration. Once again, we want to highlight that our assumption may only fit for tangible work-group activities like muscle painting with pairs of students, and may not

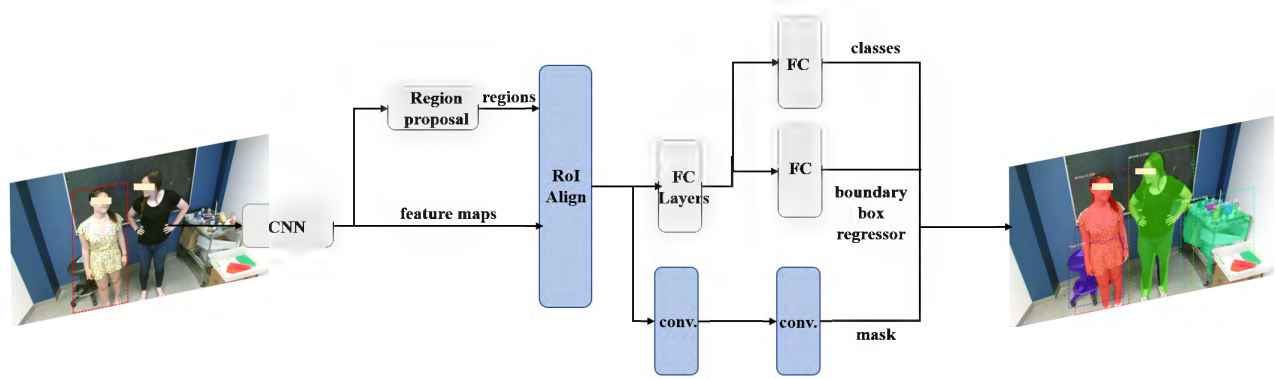

Figure 2: The Mask R-CNN framework for object detection.

Figure 3: Collaborative learning using tablet in painting activity (a) original image data, and (b) object detection using Mask R-CNN.

be generalized to other types of group-work activities which need distributed task allocations.

Figure 4: The overlapping ratio is equal to the overlapping area divided by the smaller participant area.

Overlapping Area and Ratio for Level of Collaboration. The idea for computing overlapping area and ratio came from how close two participants were during the painting activity. Since there are lots of body contacts between painters and models while collaboration study, their bounding boxes may overlap. Using the coordinates of the bounding boxes of the person instance, we calculate the overlapping area (if their bounding boxes do not overlap at all, the overlapping area and ratio will be zero) and the area for each participant (see Figure 4). The overlapping ratio is equal to the overlapping area divided by the smaller participant area. The reason for comparing the overlapping area with the smaller participant area is to eliminate the bias that

one participant may have a larger box than the other. For each group, compute the mean of all the overlapping ratio in the object detection results as the level of collaboration value.

Time on Task. We also calculated the time that students dedicated to performing the collaborative painting task. Previous work [2] shows that increased time on task is a strong predictor of knowledge retention. Un-engaged students just finish the activity in the minimum possible time. In this case, we consider time on task as one of the indicators of student engagement as well. The longer time they spend, the better the collaborative performance they have. This indicator is computed by the file names of the image data and the number of images for each group (aka time-stamped file information).

Since the treatment group use the mobile learning technology [4] during the muscle painting activity, we hypothesize that teams of students who use the tablet have better collaborative performance than the control group. In comparison to the control group who use the textbook, students in the treatment group collaborate more with each other within proximate distance and they may spend more time on task in the collaborative activity.

5. RESULTS

Participants. Total of 66 (39 Female) students in 33 teams participated in this study. 17 out of 33 pairs were in the treatment group (14 Female), and 16 pairs were in the control group (25 Female). A summary of the results from these participants is reported in Table 1.

Level of Collaboration. Among 33 teams, we calculated level of collaboration using the aforementioned method, and compared the treatment group versus the control group. The results showed that there was a statistically significant difference between these two groups based on level of collaboration; $F_{(1,33)} = 11.42$, $p < 0.005$, Cohen's $d = 1.18$ (large effect size).

Time on Task. Similarly, treatment group had a meaningful difference with control group based on time on task $F_{(1,33)} = 4.29$, $p < 0.05$, Cohen's $d = 0.72$ (relatively large effect size).

Table 1: Summary of the descriptive analytic for two groups of the study.

Groups	Level of Collaboration (%) ¹	Time on Task (seconds)
	Mean ($\pm SD$)	Mean ($\pm SD$)
Treatment	9.23 \pm 2.85	631.18 \pm 353.75
Control	6.39 \pm 1.84	428.75 \pm 170.64

¹Level of collaboration was measured based on the percentage of overlapping area of students while working on the painting task.

Figure 5: The box plots of Level on Collaboration and Time on Task for treatment and control groups in the study.

According to the results, collaboration level and time on task had large effect size values and high level of significance which indicated that both two indicators have identified the variations among treatment and control conditions successfully. Based on Figure 5 (a and b), the treatment group had higher means and more able to achieve higher value in both indicators. That means, by using mobile tablets, students were able to get closer to each other and would like to spend more time to complete the task than use textbooks. During the activity, teams with the tablet were more likely to share the contents and discuss with teammates in a close distance. Therefore, we could recognize the treatment performed better than the control groups during collaborative learning. Thus, our pre-trained Mask R-CNN approach can provide useful features, and can be used for collaborative learning analysis with acceptable accuracy.

6. CONCLUSION AND FUTURE WORK

In this paper, we used Mask R-CNN, an object detection approach, to analyze the quality of collaboration. We then evaluated the approach with two collaborative indicators related to team's proximity and time on task. The results showed that our approach was capable of recognizing differences in the level of collaboration among students in treatment versus control groups. Both the time on task and level of collaboration could successfully distinguish the differences between two groups of the study.

The focus of current project is understanding collaboration on muscle painting activity. Some aspects of our work could

be improved in the future. We plan to use our survey data as another dimension to perform collaboration evaluation. We also aim to hand-annotate part of our collected data based on the object categories we need, including painting brush, and re-train our model on the entire data set. We will work on other collaborative features, such as facial expression recognition, emotion recognition, head, and body pose estimation, and joint attention estimation to better understand the level of collaborations among teams. Finally, we aim to use a 3D pose estimation method of the human body using a single image [3] in our future work to better understand complex interpersonal collaborations with computer vision techniques.

7. ACKNOWLEDGEMENTS

We thank Drs. Rebecca Pearlman, and Richard Shingles for integrating our study to their General Biology Lab course, laboratory technicians, and teaching assistants for assisting us on data collection, and study participants for their contributions to making this study possible. We also wish to acknowledge the support from our research collaborators Dr. Nassir Navab, and Kevin Yu for their insight in study design and development.

Design of an Elective Course Recommendation System for University Environment

Boxuan MA
Graduate School of Information Science and Electrical Engineering
Kyushu University
Fukuoka, Japan
ma.boxuan.611@s.kyushu-u.ac.jp

ABSTRACT

Course recommendation system is a useful tool that not only helps the students who have no sufficient experience to decide what they should study, but also leverages their full performance if they could study what they like or are interested in. Different from MOOCs, the selection and recommendation for hybrid learning environments such as university are relatively difficult. Students who enrolled in the same course may have completely different purposes and different interest. Employing the enrollment record data from Kyushu University, we conduct a systematic investigation on the course-taking pattern for recommendation. We then discuss the challenges to recommend suitable courses in university and propose a preliminary approach to address the challenges by designing a course recommendation mechanism based on association rule of previous course-taking pattern together with student interest.

Learning Analytics; Hybrid Learning Environments; Data Mining; Association Analysis; Recommender Systems

1. INTRODUCTION

Course recommendation is considered a challenging domain that could help students in suggesting suitable courses for them as well as reducing time to explore courses that they will take. To provide suggestions to assist learners who have no sufficient experience to choose courses which they need, researchers have tried to develop various approaches to recommend relevant learning materials to learners for MOOCs. Although MOOCs have their own benefits, they are inherently limited in supporting learners in physically co-located environments such as classrooms and group/peer learning spaces. The selection and recommendation at university are often different from those in MOOCs.

Courses in university environments are closely interwoven with various types of physical, pedagogical and social contexts. There are required courses and elective courses in university. Students generally receive a grade and academic credit after completion of the course and they need to get enough credits to meet the requirements of graduation. It is difficult for students to decide which courses they should take because there are a

large number of elective courses opened in each semester, they have to spend a lot of time for exploring those courses, and they may not be able to explore all of them. Also, student interest and goal can change as they explore and discover something meaningful on and off campus, and there are complex constraints and contexts that have to be considered in choosing courses.

(1) Complex constraints

Different from MOOCs, various courses are provided for each academic year, however, students usually do not choose many courses because learning a course is a time-consuming task. In Kyushu University, for instance, statistics show that each course usually lasts for several weeks and a student enrolls in 14 courses on average each year. Moreover, students may take courses in the first two years mostly, because they may busy for internship or finding jobs in the third and fourth year.

(2) Anti-interest

Students may not choose courses based purely on their interest in university environment. For example, some students would not enroll in a course which contains contents they are interested in, they just choose the course that allow them to get credits easily. In addition, student enrollment behavior may be influenced if they are not familiar with the contents of those courses.

(3) Long-tail effect

Long-tail effect is a classic problem in recommendation system. For Kyushu University, figure 1 shows the long-tail distribution of course popularity. There are several popular courses which will be filled up quickly while most of courses will not be selected by students frequently. Those courses may disappear because there are not enough students follow.

Figure 1. Long-tail distribution of course popularity.

2. RELATED WORK

Various approaches have been used in applications for course recommendation. Content-based filtering approach recommends an item to a user by considering the description of the item and clustering the item and the user into groups to gain similarity between them. Piao and Breslin [1] propose a strategy to extract user profile text from their LinkedIn pages and to calculate the similarity with course profile text, then give the recommendation results by the similarity. Apaza et al. [2] use LDA to train two different topic models on both college course syllabus and online course syllabus then a content-based match algorithm is used to estimate the ratings from a user to all courses.

Collaborative filtering approach recommends an item to a user by investigating the user's similarity with the user's information in a system and predict the item that the user would be interested in. Hana [3] introduces a mechanism based on this approach to recommend courses for a student by exploring the student's academic record and matching the record with others' ones to gain the similarity. Then the system figures out and recommends which course he is good at or interested in so that he could pass the course. Elham S.Khorasani et al. [4] proposes a Markov Chain Collaborative Filtering model to recommend courses based on historical academic data with concerns of the sequence of each course being taken. X.Jing and J.Tang [5] use LDA to extract user-specific latent information from their historical access behaviors to represent their interest profile. Then the similarity is calculated from above interest profile, and recommend outcomes are given based on the similarity. Kiratijuta et al. [6] developed an elective course recommendation system which investigates each student's academic records to find the similarity with the targeted student.

Association rules based on frequent patterns are often used to discover interesting relations between variables in databases. In terms of course enrollment, the objective is to extract rules from data that describe previous course selections from students in higher education. Aher and Lobo [7] use association rule mining together with clustering to recommend courses by using historical data. Narimel Bendakir and Esma A. Imeur [8] presented a course recommendation system, which incorporates association rule and user ratings in recommendation. Parameswaren et al. [9] propose a course recommendation mechanism for university students, which consider complex constraints.

Compared with previous studies, the main contribution of our work is that we exploit student interest and use that to improve the traditional association rule. In addition, we use other information including course relation and social contexts to boost the recommendation performance. We designed our framework to combine them in order to make better use of available information.

3. PRELIMINARYWORK

This is a research project in its earlier stages. Currently, we collected approximately 38,968 pseudonymized enrollment records from 2,366 students. These students enrolled in 2015 at Kyushu University. And then we propose a preliminary approach and try to address those challenges above. In particular, we first analyzed the records of university student course-taking patterns by using the association rule analysis. Besides, learner

interest is used to better reveal students' potential choice and increase the diversity and abundance of recommendation results.

3.1 Association rule

It is useful for taking advantage of the collaborative experience of the students who have finished their studies. However, in the traditional association rule method, the importance of each item in the database is the same, this kind of course recommendation based on support threshold and confidence threshold is not enough. For example, some courses with good contents are excluded because the amounts of selection are lower than the support threshold. Also, the popular courses have been frequently extracted since they have been selected many times, but students may not have much interest in them. As a result, most of the recommended courses come from the relatively popular courses, however, those courses are not necessarily the ones that students are most interested in. Finally, students may be misled to choose those popular courses and other courses may disappear because there are not enough students follow.

In our framework, we plan to use interest to reflect the different importance of each course to recommend suitable contents for students. The purpose is to recommend a wider range of courses to students, avoiding the problem of insufficient interest caused by traditional association rules.

3.2 Measures of Interest

Student interest is the most important target of our framework. We want to build a simple but universal representation of student interest which will be useful not only in course recommendation but also in other personalization tasks. Characterizing what is interesting is a difficult problem. The very definition of the word "interest" is elusive. A common solution in e-learning system is directly combining user enrollment and the tags of enrolled courses [5]. While this solution suffers from the small size of tag set and the sparsity of enrollment. In our framework, we extract student interest from student activities of courses which contain much more abundant information.

Measures of interest include objective measures and subjective measures. Objective measures of interest or objective interest criteria are measures of interest that depend only on the data and the patterns extracted from it, for example, the rating of a course from student. Subjective measures of interest or subjective interest criteria are measures that also depend on the specific needs and prior knowledge of the student.

Firstly, we divided students into different clusters based on their department. Each cluster has its own preference on courses enrolling according to the enrollment records. Then every student can take the average rating of students who belong to the same cluster as an interest weight on every course. Then, available information including student attendance, quizzes, learning activities during class and their final score in each course could be used to calculate the subjective measures. Moreover, both teachers and students write e-journals after each class, which are helpful to get feedback. This kind of feedback will imply the interest of students for a specific course, which could be considered as objective measures together with student goals.

Figure 2 illustrates an overview of the recommendation system. We first use association rule together with student interest to get rules for a certain cluster based on their department. The rules'

consequents determine a list of courses to be recommended. Then we plan to use social search and courses prerequisite to adjust the final results.

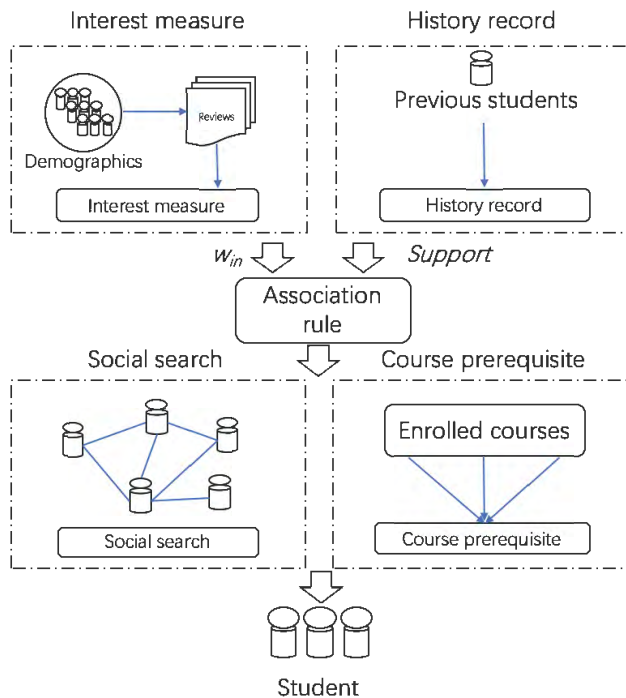

Figure 2. Overview of the recommendation framework.

4. FUTURE DIRECTION

This research aims to discuss the difference between MOOCs and university environment to recommend suitable courses for learners and study how to improve personalized course recommendation in such environment. Apart from assisting the student, it also will help the university registrar to manage courses. In particular, we propose a preliminary approach which extracts student-specific interest from e-learning system and combines association rule and student interest together to give recommend results. In addition, our approach would be helpful in other personalization situations.

As future work, social course search and course prerequisite will be used to boost our method for university environment, we will compare our framework with other recommendation system to get the evaluation result. In addition, mining other information from student behaviors to match the contents of learning materials is also an important work to do.

5. ADVICES SOUGHT

For this doctoral consortium, advice is sought regarding some concerns.

- Is this idea both significant and valuable? For example, could it be applied in a broader range of domains?*
- What kind of student data should be used for a course recommendation system? For now, we give the results only based on historical data from previous students, who have already finished the course.*
- Are there any other methods for predicting student interest for a certain course? Since the information from current student is limited, so what kind of data should be useful?*
- Are there any suggestions for the evaluation procedures of this research?*

ABSTRACT

A key issue in mathematics learning and instruction is supporting high-school students in developing problem-solving skills, which can foster creativity, innovation, and ultimately lead to success in the workplace. Towards this goal, a crucial first step is modeling students' problem-solving skills, so that effective instructions and interventions can be designed to meet their learning needs. We propose three steps to explore this direction in the domain of non-routine mathematics problems -- those that cannot be solved by a textbook procedure but require insight and resourcefulness. First, we construct a conceptual framework of the most common problem-solving strategies that our instruction and modeling process will be based on. Second, we conduct a pilot study to test whether the framework can help students generate multiple solution strategies. Third, we use natural language processing and crowdsourcing to support automated assessment of students' inputs and explanations. These three steps will contribute to an educational platform that can be deployed at scale to assist students in solving non-routine mathematics problem and serve as a blueprint for problem-solving instructions in other domains.

Keywords

Non-routine Mathematics, Student Modeling, Crowdsourcing

1. INTRODUCTION

Training students to be good problem solvers is an important focus of mathematics teaching and learning [9, 25]. However, typical mathematics instruction in U.S. classrooms too often comprises rote learning, such as memorizing the rules for solving algebraic equations, without exposing students to the reasons for those procedures or alternate ways to solve problems [8, 24]. As a result, students struggle to apply learned procedures in novel or non-routine situations where either the surface or structural features of the problem are different [3]. Not surprisingly, U.S. students have fallen far behind their counterparts in other countries on standardized tests of mathematics achievement and on tests measuring abilities to solve novel and challenging problems [18].

Addressing this issue at scale requires developing an educational platform that provides individualized instruction to students in non-routine mathematics problems. However, there are two crucial questions in this direction. First, what do we teach the students? Due to the non-routine domain's nature, there is no set

of procedures that can be used to solve all problems. Thus, we choose to focus on identifying a small number of strategies that are most widely applicable; these will serve as the *expert model*. Second, how do we evaluate student inputs and provide effective feedbacks? Recent development of tutoring systems has moved on to more complicated knowledge domains, such as protein folding [2], programming language [1], and database [17], which also require students to engage in high level problem-solving tasks. To our knowledge, however, there is no system that targets mathematics problem-solving. This domain is unique in that students have to input mathematical arguments, which are a combination of text and formula, to explain and justify their results. Therefore, our approach is to first construct a dataset of mathematical arguments and explanations through crowdsourcing, then employ natural language processing techniques trained on the dataset to assess the quality of student inputs.

2. RESEARCH PLAN

2.1 Constructing the Expert Model

Schoenfeld [21] identified non-routine problems as those: (a) without straightforward, algorithmic solutions, (b) that require ingenuity and resourcefulness to solve, and (c) with multiple solutions. A useful source of these problems is the high school textbook "Problem Solving Strategies: Crossing the River with Dogs" [12] that contains problems such as:

- Each team in a new basketball league will play one game against each of the other teams. There are seven teams: A, B, C, D, E, F, G. How many games will be played in all? (p. 32)
- Find the sum of the first 5000 odd numbers (p. 296)
- How many squares are there on an 8 x 8 grid? Note that a square can have side length from 1 to 8. (p.271)

In identifying a conceptual framework for solving these problems, we turned to the four basic principles of problem-solving outlined by Polya [19]. First, "Understand the problem" is to make sure one knows what is being given and asked. Second, "Devise a plan" involves finding the connection between the data and the unknown, then choosing an appropriate strategy, such as making an orderly list, eliminating possibilities, and looking for a pattern. Third, "Carry out the plan" means executing the chosen strategy. Finally, "Look back" is about reflecting on the problem and the solution so that one can acquire transferable insights for new problems. Guided by these principles, we have solved 70 non-routine mathematics problems from [12], which we will use as the source of instructional materials for this project. Through this exercise, we also came up with eight strategies, four of which are for "preprocessing," used to create a useful mental representation of the problem, and four of which are "solving" strategies, used to come up with a solution. Every one of the 70 problems were solved in multiple ways, using different strategies.

Huy Nguyen, John Stamper and Bruce McLaren "Towards Modeling Students' Problem-solving Skills in Non-routine Mathematics Problems" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 702 - 705

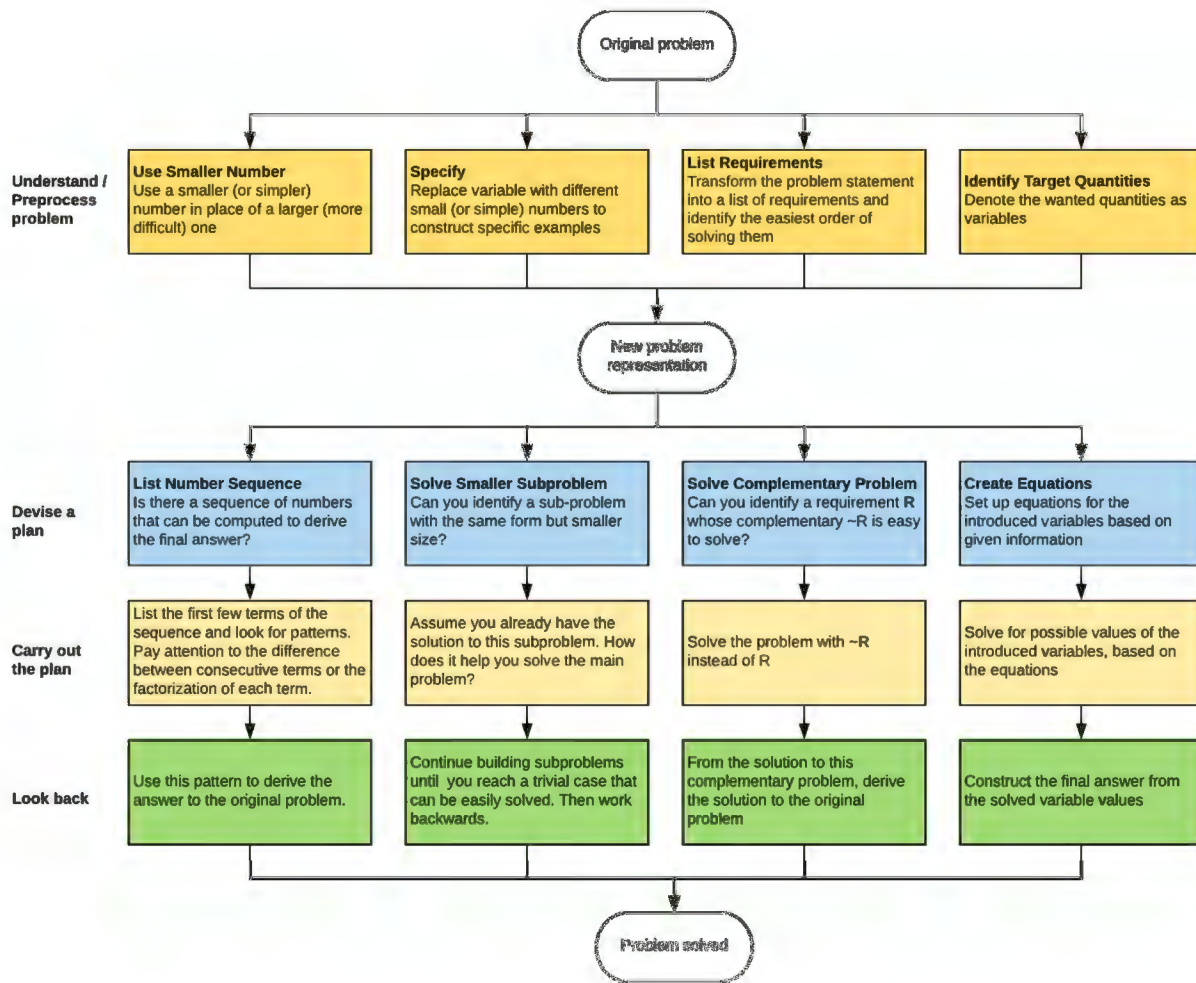

Figure 1: Non-routine problem-solving flowchart serving as the expert model.

Table 1: Materials used in the study.

Problem Statement	Comparison questions
Problem 1: How many squares are there in an 8 x 8 chessboard?	Which solution strategy do you prefer and why? Which solution strategy works better for a larger chessboard? Which solution strategy works better if the question prompt changes to “how many rectangles are there in an 8 x 8 chessboard”?
Problem 2: A number is called a decreasing number if it has two or more digits and each digit is less than the digit to its left. For example, 7,421; 964,310; and 52 are decreasing numbers but 3,241; 6,642 and 963,212 are not. How many decreasing numbers are there?	Which solution strategy do you prefer and why? Which solution strategy would work better if the definition of decreasing number change to “a number is called a decreasing number if it has between two and ten digits, and each digit is less than or equal to the digit to its left”?

To characterize problem-solving strategies -- as well as to create a representation that can be used to guide students -- we developed the flowchart in Figure 1 from solving the 70 problems, organized according to Polya’s four problem-solving stages [19].

The flowchart will serve as a scaffold as students are exposed to and practice different problem-solving strategies. It is intended to

help students select the most appropriate strategy at each stage of the problem-solving process, based on the problem features.

Once the students have selected which strategy to follow, they will be prompted to enter the arguments and explanations for each of the four steps in Figure 1.

2.2 Pilot Experiment

To test the effectiveness of the proposed framework, we will reach out to local high schools to conduct a pilot study, in which students will be shown each of the two non-routine problems in a separate paper and asked to solve it in as many ways as possible, with the aid of the flowchart. When the students succeed in coming up with one solution, they would be asked to think of another solution with a different strategy. If they could not come up with the second solution, they would be prompted to compare a given expert solution with their first solution. If they could not come up with any solution (due to time limit or being stuck), they would be shown one solution strategy, then another. We also rotate the order of solution strategies for each student. Finally, once students have two solutions, they are asked to compare the two with a number of prompting questions. The problem statements, selected from [12], and comparison questions used in the study are listed in Table 1.

Students will be interviewed separately for about an hour and asked to think aloud while solving the problems / evaluating the solutions. Their written solutions and scratch papers, in addition to think-aloud records, will be used for preliminary data analysis and student modeling.

2.3 Constructing the Student Model

An important component of our educational platform will be its capability to assess student explanations generated during problem-solving and providing feedback on and guidance for those explanations. To achieve this, we propose to combine multiple sources of data, both domain-general and domain-specific, to build the training dataset for this task. Our first data source will be domain-general, built from online math problem-solving datasets that include solutions and explanations for math word problems. Three datasets that we will explore are those from the Google DeepMind project [15], the Stanford Natural Language Inference (SNLI) Corpus [4] and e-SNLI, a large corpus of explanations for the SNLI dataset [5]. Our second, domain-specific dataset will be crowdsourced. We will use 100 Amazon Mechanical Turkers to collect explanations for each step of each of 15 non-routine mathematics problems (times 2 solutions for each problem) that we will use in our study. In other words, each of the 100 Turkers will be presented with 30 problems and will be tasked with providing explanations for each of the steps in each solution. We will then manually code these explanations according to their quality. Given the coded data, we will experiment with a variety of deep learning models to classify the quality of student inputs. We will explore several variations of Sequence Models and Convolutional Neural Networks coupled with Transfer Learning, as informed by state-of-the-art research results achieved by Howard and Ruder [10]. They proposed Universal Language Model Fine-tuning that reduced current text classification errors by 18%-24% in tasks such as Sentiment Analysis and Topic Detection. We will also experiment with the question classification method used by [20] that achieved high accuracy. In addition, once we have a fully-fleshed coding scheme for explanations, we will look more deeply at the specific content of feedback, particularly in catering feedback to specific knowledge levels of students. After assessing the quality of student inputs at each step, we can model students' learning by Knowledge Component (KC) based modeling [13], where each KC represents one of the 12 strategy steps in Figure 1. We recognize that the level of granularity of these strategies may not be low enough for the final KC model. To address this issue, can use the students' collective performance in each KC, visualized

by learning curves [7] in DataShop [23], in order to apply the human-machine discovery method [22] and identify potential improvements in our initial KC model (e.g., whether there is a KC that needs to be decomposed). We then can revise instructional materials for the next study iteration to identify more fine-grained KCs [14, 16]. There is also potential in KC-based student performance prediction, using a variety of techniques such as Item Response Theory [11], Bayesian Knowledge Tracing [7] and Bayesian Network [6]. Accurate predictions by the system would then allow for more effective and timely interventions, for example by offering an appropriate level of scaffolding at the beginning of a new problem.

3. CONCLUSION

In this paper, we propose a plan to model high-school students' problem solving skills through an educational platform in the domain of non-routine mathematics problems. We envision three potential applications of this platform. First, it will be accessible to a wide range of students, especially the lower performing students who are not traditionally exposed to problem solving. Second, it will provide a blueprint for automated assessment of students' explanations in an open-ended domain, which is among the central themes of the EDM community. Finally, the constructed student models could yield insights into students' problem-solving process that are applicable to other domains.

Anatomy of mobile learners: Using learning analytics to unveil learning in presence of mobile devices

Varshita Sher
School of Interactive Arts and Technology
Simon Fraser University, Canada
vsher@sfu.ca

ABSTRACT

Mobile technology has been a focus of research since the early 2000s and has attracted researchers from various disciplines ranging from pedagogical, health-care, technological to app developers. In recent times, there has been a substantial interest in capitalizing on the abundance and the ubiquity of these technologies for their educational use. However, the role of mobile phones in educational setting is still largely under-researched. Similarly, little attention has been paid to the research on the extension of learning analytics to analyze the learning processes and strategies of students adopting mobile platforms. Traditionally, the research into mobile learning has mainly relied upon self-reported data. While literature has evidence that survey data facilitates extraction of invaluable information, it suffers from a significant shortcoming - unreliability due to learner bias and poor recall. Therefore, this paper outlines the doctoral research project that explores the use of mobile technology in educational context using data mining techniques and learning analytics methods to analyze digital trace data and provide insights into how students learn. The results so far have enabled us to categorize students as adopting one of the three technological modality strategies - strategic, minimalist, and intensive - based on how extensive the use of multiple modalities (such as desktops, tablets, smartphones) is for learning activities and their final academic performance. Our results also provide evidence suggesting incorporation of the modality used by the learner, for carrying out an activity, as a viable feature in learner models helps in improving the prediction power of these models.

Learning Analytics, Mobile Learning, Trace Analysis

1. INTRODUCTION

Mobile technology has been a focus of research since the early 2000s and has attracted researchers from various disciplines ranging from pedagogical, health-care, educational,

technological to app developers. An October 2011 article in *The Economist* posited that, with the number of PCs already surpassing 1 billion in 2008, the number of mobile devices too would reach 10 billion in 2020 [2]. However, even with the proliferation of mobile phones at such an unprecedented rate, their role in the educational setting is still largely under-researched [1, 12]. The challenge for educators and designers, thus, is one of understanding and exploring how best students might use mobile technology to support learning. This challenge is further complicated by the fact that while there exist plethora of learning analytics dashboards (LADs), there is a critical paucity of mobile learning analytics dashboard applications [11] in comparison to their desktop counterpart. The desktop LADs have been extensively researched in terms of their usability, learner strategies, usefulness, effectiveness, and efficiency using complex data mining techniques and learning analytics methods. On the contrary, little attention has been paid to the research on the extension of learning analytics to analyze the learning process of students adopting mobile platforms. The very few extant mobile LADs [5, 10, 7, 4] adopted by students have been analyzed mostly using self-reported data typically collected through questionnaires or think-aloud protocols, which suffer from unreliability issues due to learner bias and poor recall. Moreover, we are still unaware of the impact of the 'source' of log files (from different devices), if any, on the outcome prediction in learner models.

Thus, our research aims to bridge all the previously discussed gaps and explore the use of mobile technology in an educational context. It aims to provide a holistic understanding of learning in presence of mobile devices and its impact on learning - right from the identification of learning strategies employed by mobile learners, to the learning activities benefiting the most from mobile technology (w.r.t. online discussions and course assignments), and to the construction of technological modality-specific learner models for learning outcome prediction. We focus on using advanced data mining techniques and learning analytics methods to analyze digital trace data and provide insights into how students learn using different technological modalities, with main focus on mobile devices.

1.1 Research Question I

The first goal of the proposed research is to explore how mobile devices are used when regulating learning via learning management systems (LMS) in the context of blended courses. To do so, we mine the sequence data from student

Varshita Sher "Anatomy of mobile learners: Using learning analytics to unveil learning in presence of mobile devices" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 706 - 709

logs to examine the extent to which various technological modalities (including mobile devices, laptops and desktop PCs) are either used sequentially and/or simultaneously and assess their potential to influence the overall academic performance and study habits at various learning activities. In order to achieve that, we study the following two research questions:

RQ1.1: *Can we detect patterns in students' use of multiple modalities that are indicative of their adopted technological modality strategy when using an LMS tool? If so, what kind of strategies emerge?*

RQ1.2: *Is there an association of the identified strategies with students' performance in online discussions and overall academic performance?*

1.2 Research Question II

Central to the idea of mobile learning is that learning can occur context-free; across different places and at different times and not confined to the formal classroom settings. While location-aware mobile learning systems has been widely studied, albeit using descriptive statistics only, even lesser attention has been given to the temporal aspect of the use of these mobile technologies. That is to say, not much is known of the associations between different modalities (such as desktops, mobiles and tablets) and the time of the day during which the modality-learner interactions take place. We assess the associations of time of the day they learn, not only with the frequency of usage of a modality, but with the sequential patterns of usage of different modalities in a blended course. Knowledge of the personally-negotiated learning time-frames, mediated by different modalities are conducive to timely, personally tailored feedback, reinforcing the 'right information at right time' learning motto. In order to achieve that, we study the following research question:

RQ2: *Are there any underlying associations between time of the day and the patterns of modality usage based on a learner's modality-use profile?*

1.3 Research Question III

The introduction of mobile technology as a pedagogical tool has witnessed many enthusiastic supporters who successfully incorporate mobility in their everyday learning routine. However, it is still unclear what dictates the students' decision to adopt or resist mobile technology in the first place. The following research questions ascertain whether learners' patterns of modality usage are driven by their inherent student characteristics or the type of activities they must engage in.

RQ3: *Do students use technological modalities differently when engaging with different types of learning activities (say, Assignments and Online Discussions)?*

1.4 Research Question IV

The research area of analyzing log file trace data to build academic performance prediction models has tremendous potential for pedagogical support. Currently, these learner models are developed from logs that are composed of one

intermixed stream of data, treated in the same manner regardless of which platform (mobile, desktops) the data came from. Given that learners use a combination of devices when engaging in learning activities, it is apparent that weighing the logs based on the platform they originate from might generate different (possibly better) models, with varying priority assigned to different model features. For instance, frequency of course material access might be a less powerful indicator of academic performance compared to the frequency of course material access 'from mobile devices', probably due to the benefits associated with ubiquitous any-time access available to mobile learners. Thus, the primary goal of this research question is to bring to light the potential for improvement of prediction power of models after considering the learner's platform of access while generating learner models for predictive analysis.

RQ4: *To what extent is the predictive strength of LMS features influenced by distinguishing the modality of learner access when predicting course grade??*

2. POTENTIAL CONTRIBUTIONS

The research on mobile learning has primarily focused on studying the *effectiveness* or *design* of the mobile learning systems [13]. There are two major flaws to this. Firstly, as pointed out by [6], *it is the learner that is mobile, rather than the technology*. Hence, while the research focused on designing of specific portable technologies has been useful, it is now time to dig deeper into complex interactions between learners, mobile devices, learning activities, and available learning materials (briefly touched upon by [1]).

Furthermore, assessments of effectiveness of mobile learning systems are generally conducted using overly general, broad surveys and self-reported questionnaire, usually in a lab setting. The traditional surveys have been recognized as highly flawed in the educational research community due to unreliable issues stemming from learner bias and poor recall and the extremely controlled environment in lab settings deters the observation of learners' actions, decisions and learning strategy choices in their natural environment (thereby threatening external validity of experiment). Consequently, the studies have only sufficed in making superficial claims about *trends* in mobile learning, using simple analyses such as aggregates and percentages - *20% people prefer to use mobile phones for participation in the discussion activity*. This is insufficient for the explication of the actual way in which mobile technology is impacting the everyday learning process in authentic educational settings wherein interleaved pattern of usage are observed which up until now have been understudied [8, 9]. This is exactly what my doctoral thesis will cater to. The advantages of analyzing such patterns is three-fold. It supports instructors in blended courses through more refined interpretation of students' actions in the LMS when participating in the learning activity. For learners, this allows for recognition of strategies (comprising modality-action pairs) that maximizes student's learning achievements and helps in refraining from suboptimal learning strategies. It is equally useful for future LMS designers when designing notification systems that are capable of sending reminders for modality-specific learning actions.

3. METHOD AND CURRENT PROGRESS

In my research, I am analyzing the data produced by the second and third year undergraduate students in two programming oriented courses at a Canadian university. Currently, the data has been collected from two semesters (Fall 2017 and Spring 2018) and is being continually logged from subsequent offerings of the two courses. Each course spans over 13 weeks and for the two semesters, a combined enrollment of 121 students (83+38) was observed. The courses use blended delivery, utilizing the university's learning management system (LMS) to support learning activities and students' overall schoolwork. The LMS hosts access to reading material, posted lecture slides, tutorial materials, general course information, weekly or bi-weekly course assignments, assignment submission, grades, and allows participation in online discussion activities. In addition to the web-browser versions of the LMS (desktop/laptop/mobile), students have access to the mobile app version provided by the LMS vendor. Comparison of the features and functionalities offered by the two versions have revealed no apparent differences.

I plan to carry out my research in four phases, one for each research question. At the current stage, I am working on phase 2 and 3, having completed and submitted research questions from phase 1 (accepted) and phase 4 (in review). Hence, in this section, I will briefly touch upon the methodology used (or intend to use) for each of these research questions and the results obtained so far.

3.1 RQ1

In order to examine the presence of patterns in students' use of several technological modalities, I encoded each learning session as a sequence of modalities (used to carry out each action in that learning sessions) using a representation format of the TraMineR R package [3]. These sequences were clustered using agglomerative clustering based on Ward's method. The computation of the distance (similarity) between sequences, required for the clustering algorithm, was based on the optimal matching distance metric [3]. The sequence clustering algorithm produced four clusters, i.e. technological-modality profiles - Diverse (use of many different modalities), Mobile-oriented, Short-desktop and Desktop. Next, the students were clustered, based on how many of their sequences belong in each modality profile, using Euclidean metric to compute the distance between vectors. As a result, three student clusters (Strategic, Minimalist and Intensive), representative of their modality strategies, were obtained.

To examine if there was a significant difference between the identified student groups, we performed a multivariate analysis of variance (MANOVA). The student cluster assignment was treated as the single, independent variable along with following dependent variables: overall academic score, counts and time spent on viewing, posting and replying to messages along with the word counts and quality of messages in discussion board. I found a moderate effect size ($\epsilon^2 = 0.12$) of students' adopted strategies on the final course grade. Furthermore, when looking specifically at online discussion engagement and performance, students' adopted technological modality strategies explained a large amount of variance ($\eta^2 = 0.68$) in their engagement and quality of contributions.

3.2 RQ2

For this question, I have encoded learning sessions from all students (as was done in RQ1), followed by categorizing each learning session into one of the four broad TOD (time of the day) categories, intuitively: Morning (5 - 11 a.m.), Afternoon (11 a.m. - 4p.m.), Evening (4 - 7 p.m.) and Night (7 p.m. - 5 a.m.). To examine if there was an overall significant relation between the modality-profile of learning sessions and the time of the day each of these sessions took place, a chi-square test of independence was performed across all learning sessions after summarizing data, composed of each sessions' technological modality profile cluster and the TOD category it belongs to, in a two-way contingency matrix. The analyses was replicated across each of the three modality strategies (obtained in RQ1) and results revealed significant associations for all three strategies. However, there were significant differences with respect to the preferred time of the day for carrying out learning sessions belonging to each modality profile, based on the learner's modality strategy. For instance, mobile-oriented learning sessions were carried out mostly in the afternoon by strategic and intensive learners but in the morning by minimalist learners.

3.3 RQ3

The ongoing activities for this research question are mainly focused on preliminary data analysis. I have encoded the learning sequences, from two main learning activities i.e. assignment and online discussions, as representations of the TraMineR format. For each learning activity, the sequence clustering based on optimal matching metric resulted in four and three technological modality profiles (TMP), respectively. Consequently, two different partitioning of the students, one based on TMP clusters from online discussion activity and the other based on TMP clusters from assignment activity, both resulted in 3 student clusters each.

The initial exploratory analysis comparing the two student clusterings, obtained from the two learning activities, revealed a rand index of 0.48, meaning that the two clustering agree to a very small extent only. Therefore, we posit with some certainty that the learner's patterns of modality usage (or in short their choice of technological modality strategy) is dependent on the learning activity they are engaging in. To further strengthen this claim, we look at the rand indices obtained from the two learning activities when compared to the benchmark student classification (from RQ1). The benchmark classification corresponds to the student strategies (i.e. clusters) that are gauged from their overall engagement with the LMS and reflect the *generic* or habitual patterns of use of different modalities (and thus considered analogous to a student's innate characteristics). We found a large overlap (rand index = 0.85) of strategies in the benchmark classification with the assignment activity but only a small overlap (rand index = 0.51) with online discussion activity. This indicates that, in addition to the strategies from the two learning activities being different, the strategies from one of them (i.e. assignment activity) *more* closely resemble the strategies in the benchmark classification, compared to the other (i.e. discussion activity). As with any speculation, follow up inferential analysis will be required to solidify our claims.

3.4 RQ4

To investigate the effect of modality on different types of commonly included learning-related activities (Table 1) and their traces in the online courses, I selected 10 features (5 counts + 5 time spents for each activity) for inclusion in my analyses as predictors of academic success. Variables derived from the LMS trace data include: syllabus, course material (lecture + tutorial slides and instructor provided supplementary material), assignments, feedback on the assignments and calendar. For each student I extracted the number of times (and the time spent on) using a particular feature by aggregating individual operations. I call these variables *LMS features*. Each of these variables was split up further to account for the platform used to access that particular feature. For instance, in addition to having the total number of assignment views for a student, I computed three more variables – mobile views, desktop views and tablet views – which indicate the respective number of assignment views from each of the three main modalities. I call such variables *Modality features*.

Next, I conducted a series of regression analyses with course grade as the outcome variable in each. For each of the ten learning features, two regression models were built using (a) LMS features and (b) Modality features. The results reflected that for each of the ten features, an increase in R^2 from Model 1 to Model 2 was observed. This increase accounts for the percentage of variability in student course grade explained by the Modality features over and above the LMS feature. An ANOVA analysis using F-test of the statistical significance was conducted to ascertain whether the increase was statistically significant and it was found to be significant for more than 50% of the variables tested.

4. ADVICE SOUGHT

My research is at an intermediate stage and I hope the consortium could provide me some guidance and insights in the following areas:

- I am interested to know if there is a method, especially in the area of network analysis that can help me assess the (direction and frequency of) transitions between mobiles, desktops and tablets, and how these transitions differ when learners are engaging in different learning activities.
- For RQ3, while I am focusing on chi-square test of independence to test associations between time of the day and modality patterns, for the next steps I need to know how to identifying/interpret patterns using the time-series analysis. Also, how can I account for the ‘random noise’ that might be introduced from students’ use of different devices for non-educational purposes?

5. ACKNOWLEDGMENTS

This research was supported by Natural Sciences and Engineering Research Council of Canada (NSERC) and Social Sciences and Humanities Research Council of Canada (SSHRC).

Modeling Student Performance and Disengagement Using Decomposition of Response Time Data

Deniz Sonmez Unal

des204@pitt.edu

ABSTRACT

Students' first response time has been used as a key predictor in various types of models in order to predict student performance and engagement. However, the effect of how much time students spend on particular activities within a single response time remained unexplored. In this paper, we divide response times into meaningful subcategories in order to provide a more accurate prediction of learning and disengagement. We fit a model with the derived subcategories and show how this model outperforms the baseline model that uses the raw response times. We present the early findings of our ongoing work and seek advice on how the insight that we get from these findings can be used in further detection of student off-task behavior.

Keywords

Student modeling, Response time, Disengagement, Regression models

1. INTRODUCTION

Various types of models of student learning from intelligent tutoring systems leverage response times in order to better predict student performance. For example, Xiong et al. [10] compared a baseline random forest model to another model with response times and related features added. They found that adding response time could make a (small but) significant improvement in predicting student performance. Wang et al. [9] included response time information in knowledge tracing algorithm and found that adding response time improved KT's accuracy. People have also used response times in their models to explain whether students are engaged with the system they are interacting. Beck developed a model [2] based on item response theory which was able to give an estimate of the probability of a correct response given a response time for modeling disengagement over time. Shih et al. [7] developed a model that shows some behaviors previously shown as negatively correlated with learning can actually be beneficial for some students. In general, much of this research is based on the hypothesis that if a student responds to a problem step too quickly or too slowly, they are likely to be unsuccessful in that particular step and if students do this too frequently, they tend to perform worse on the task.

However, something that is less explored is how much time students are spending on different activities within a single response time and how it is affecting how they perform on tasks. If we take a reading task for example, we would need an estimate of how long it takes a student to read a given text so that we could tell when a student is switching from one engaged state (reading) to another (thinking about the step/reflection) or an off-task/disengaged state. Shih's model used estimates of unobserved activities during a single response time to show that repeatedly asking for hints might not always be a harmful behavior. Our work is similar to Shih's work in a way we are trying to estimate how much time students spend on activities we cannot directly observe from the log data, but our activities of interest are different as Shih is focusing on activities can be observed in a problem solving domain, while we are interested in a reading task.

The goal of our work is to decompose response times into meaningful subcategories in order to provide a more accurate prediction of learning and disengagement.

2. PROPOSED CONTRIBUTIONS

In this work, we propose to develop a new model that leverages time information to predict student performance and disengagement. In order to achieve this goal, we will use the log data collected from EMBRACE [8]. EMBRACE is an iPad application designed to improve English reading comprehension of young native Spanish speaker students. Students are reading interactive story books by chapters and answer multiple choice questions related to the story at the end of each chapter. While students are reading, some of the sentences are highlighted with a blue color. In those sentences, students are asked to move images shown on the screen to represent what they read (see Figure 1). The control version of EMBRACE does not have this feature. In this version, student actions are restricted to reading a sentence, tapping on a word to hear its pronunciation, and moving forward to see the next sentence. We start to analyze the response time from the control version. Since the student actions are limited, we can get a clearer idea about how predictive the subcategories of response times we derive. As the students can be either reading the sentence or thinking about it (assuming they are engaged with the system) in the control version, we initially decompose response time into **reading time** and **thinking time**. Reading time is the estimated time for a student to read the sentence and thinking time is the remaining time when we subtract reading time from the raw response time (the total time spent on a sentence).

Figure 1. Screenshot from EMBRACE

However, the student can be in a disengaged or an off-task state during reading. If that is the case, some part of what we identify as thinking time will be actually the time spent in these unproductive states. We are interested in finding in what portion of thinking time students are in these states. Since often being in these states are found to be negatively correlated with learning [1], the student performance within periods of thinking time may be indicative of their cognitive state. Our proposed approach to detect these states is to estimate the break points where the relationship between thinking time and the student performance changes. We are targeting identifying these states based on the different relationships in the regions that are defined by the estimated break points and frequency of specific student behavior such as help requests or trying to skip through sentences.

With the insight gained from the control version, our next step will be to leverage this approach to identify different student behaviors within response times to more complex actions in other versions of EMBRACE. We are aiming to provide better predictions of student performance and identify student cognitive states such as reflection, gaming the system, mind wandering, and wheel spinning based on the time information in a larger set of student actions.

3. METHODS & PRELIMINARY RESULTS

3.1 Data

Our data comes from the logs collected from 22 students interacting with the control version of EMBRACE. Students are reading 35 chapters and answering questions at the end of each chapter. Our measure of student performance is the proportion of correctly answered questions in the comprehension assessment in each chapter. We extract the time a student spends on each sentence in a chapter and calculate the mean response time in each chapter. Some students had unrealistic response times (due to logging errors) or missing assessment scores in some of the chapters, such student chapter pairs are excluded from the dataset. This left us 742 data points (student chapter pairs).

3.2 Estimating Likely Reading Time

Since the actual time that students take to read a sentence is not logged in the application, we estimate how long it should take them based on students' decoding ability and how many words a particular sentence contains.

The reading time was estimated for each sentence as word count in the sentence divided by how many words the student should be reading per minute based on their decoding ability. Students' decoding ability is measured by their scores on the decoding part of the Qualitative Reading Inventory (QRI) [3].

In order to get the words per minute for each student, we used the guidelines from [4]. This gives lower and upper bounds for how many words a student should be reading per minute based on what grade the student is in.

Instead of making predictions about reading time based on grade, we make predictions about reading time based on QRI scores. We perform this mapping as follows:

$$f(t) = c + \left(\frac{d - c}{b - a} \right) * (t - a)$$

where interval $[a, b]$ denotes our QRI range, $[c, d]$ denotes the wpm range for students from 2nd to 4th grade in [4], and t is a specific QRI score.

Our QRI range is $[10, 40]$ and the words per minute range that we picked from Morris's guideline is $[80, 150]$. Based on our mapping function, if a student got 33 on QRI, they are estimated to be reading $80 + ((70)/(30)) * (33 - 10) \sim 134$ words per minute. Using the same function, if a student got 10 on QRI their wpm estimation is 80 and if a student got 40 on QRI their wpm estimation is 150.

3.3 Estimating Likely Thinking Time

We simply calculated the thinking time by subtracting the estimated reading time from the response time logged in the application. If we call the sentence time ST , where ST is the mean time spent on sentences in a chapter and call estimated reading time ERT where ERT is the mean of reading time for a student in a chapter based on student's QRI score and the word count in a sentence. Then thinking time TT is calculated as follows:

$$TT = ST - ERT$$

If a student requested help (tapped on a word to hear its pronunciation) on a sentence, we subtract the time the student spends on listening to the help audio (help time) from thinking time. Help time is calculated as number of help requests on a sentence multiplied by two, as help is a single word read to the student twice, which roughly equates to two seconds.

3.4 Predicting Student Performance

We built a piecewise linear regression with students' mean thinking time on chapters, mean frequency of help requests, mean frequency of attempt to skip, and students' pre-test scores on different English language proficiency assessments (SELPS, QRI, Gates) as predictors and students' correct answer proportion on comprehension assessment tests given at the end of each chapter as the outcome variable.

We used the 'segmented' function in R [5, 6] to build the piecewise model. It takes potential breakpoints for one or more predictors as an input, and fits a piecewise linear function based on those breakpoints (each region, as denoted by two adjacent breakpoints, is fit with a linear regression). The function iterates over possible breakpoints, starting from the user-input breakpoints, until it finds an optimal set of breakpoints.

We decided on three breakpoints for the thinking time variable as we expect to see four different relationships and four different states that can be identified by these relationships: 1) Probably

gaming / Not taking enough time to think, 2) Reflection / Thinking deeply about the sentence, 3) Wheel-spinning / Struggling to understand the sentence, 4) Mind-wandering / Possibly thinking about something else other than the sentence. We picked the initial breakpoints using mean and standard deviation of thinking time. Our first break point is one standard deviation below the mean (-1.95 s), our second break point is the mean thinking time (3.99 s), and our third break point is one standard deviation above the mean (9.93 s).

Figure 2. Relationship Between Students' Mean Thinking Time and Correct Answer Proportion

The segmented function estimated the break points at -1.41 s, 4.30 s, and 14.26 s. The resulting segmented model accounted for 21% of the variance ($R^2 = .21$, $F(12, 704) = 16.43$, $p < .01$). The results showed that thinking time ($\beta = -1.36$, $p < .05$), mean frequency of skip attempts ($\beta = -.13$, $p < .001$), English SELPS scores ($\beta = .19$, $p < .001$), and Gates scores ($\beta = .17$, $p < .001$) significantly predicted correct answer proportions.

As a comparison point, we fitted a linear model with the same predictors and the same outcome variable. The resulting linear model could account for 14% of the variance ($R^2 = .14$, $F(6, 710) = 20.13$, $p < .01$). It was found that thinking time ($\beta = .16$, $p < .001$), mean frequency of skip attempts ($\beta = -.16$, $p < .001$), English SELPS scores ($\beta = .18$, $p < .001$), and Gates scores ($\beta = .13$, $p < .01$) significantly predicted correct answer proportions. To statistically compare the linear model to the segmented model we used 'anova' function (which does an F-test) in R. Table 1 shows including the segments in thinking time variable reduces the residual sum of squares significantly which is indicating that the segmented model is a better fit for the data.

Table 1. Comparison of Linear and Segmented Models with Thinking Time

Model	Res. Df	RSS	Df	Sum of Sq	F	Pr(>F)
Linear Model	710	51.408				
Segmented Model	704	46.988	6	4.4199	11.037	8.859e-12

In order to see if using thinking time instead of the raw response time variable extracted from the log data can provide a better fit, we built another piecewise regression model similar to our first model. Instead of thinking time this model uses raw response time as a predictor and estimates the break points on this variable by using its mean and standard deviation values. This model accounted

for 18% of the variance ($R^2 = .18$, $F(12, 704) = 13.32$, $p < .01$). The raw response time ($\beta = -7.08$, $p < .05$), mean frequency of skip attempts ($\beta = -.18$, $p < .001$), English SELPS scores ($\beta = .19$, $p < .001$), and Gates scores ($\beta = .16$, $p < .001$) found to be significant predictors of correct answer proportions. Given this, the piecewise model with the thinking time as the segmented variable gave the best overall fit. In order to compare the two segmented models, 'coxtest' function in R was used since these models are not nested. We found that the fit of the model using thinking time as the segmented variable is significantly better than the one using raw response times ($p < .001$).

Figure 2 shows how the relationship between mean thinking time and correct answer proportion is changing at these points. The relationship seems to match our expectations. In the first zone, students are spending less than a second on thinking which means that they are spending less time than we estimated on reading the sentences, too. This was interpreted as possible gaming behavior as very low time spent on sentences with very low performance on chapter can be sign of skipping the sentences without reading. In the second zone we see that with more time spent on thinking about the sentences, the student performance is reaching to its peak value. This relationship was interpreted as a sign of reflection, taking enough time to think about the sentences after reading which is helpful for better understanding the story and doing well on the comprehension assessment test in the end of the chapter. We interpret the third zone as the possible start of wheel spinning. Since student performance is not low, we anticipate that the students in this zone are not completely off-task however as thinking time increases, the performance starts to slightly decrease which means that students are spending more time on thinking than they should. This was interpreted as students starting to struggle in the sentences. The last zone was interpreted as possible mind-wandering as the time spent on thinking is quite high and as it increases the performance decreases drastically. This relationship explains that the students are not involving in task related thoughts.

Our immediate next steps include calculating the percentage of time spent in each region defined by the estimated break points for each student and seeing if there is a correlation between that and behaviors that are indicative of gaming, mind wandering or wheel spinning such as constantly trying to skip through sentences and repeated help requests.

Later we aim to apply a similar methodology in the other versions of EMBRACE where students can perform more complicated actions. We are interested in finding out different possible subcategories of response time and how they can be used to model student behavior in the richer data.

4. ADVICE SOUGHT

For this doctoral consortium, we would like advice regarding the following concerns:

- 1) What are meaningful sub-categories of response time when student actions are not limited to reading only but they are actually interacting with the application by moving images they see step by step?
- 2) In what ways can the relationship between thinking time and student performance be interpreted? How can it relate to student disengagement or off task behaviors and how can this relationship be validated?
- 3) What suggestions in general do you have for the methods we are using to find sub-categories within response time.

Your feedback on these three aspects of our research will be very insightful for us as we are continuing our work with the data from other EMBRACE versions with more complex student actions.

5. ACKNOWLEDGEMENTS

I would like to express my sincere thanks to Erin Walker for her guidance and valuable comments. I also would like to thank M. Adelaida Restrepo, Arthur Glenberg, and Ligia Gomez for useful discussions and their support. This paper is based upon work supported by the National Science Foundation Grant # 1324807.

Techniques for Automatically Evaluating Machine-Generated Questions

Zichao Wang
Rice University
Houston, TX 77005
jzwang@rice.edu

ABSTRACT

Recent work [16] has demonstrated the superior quality of questions generated by state-of-the-art neural question generation algorithms. However, evaluating the quality of these questions typically requires a domain expert which is labor intensive and costly. We therefore seek an reliable and *automatic* method to evaluate the quality of the questions. To this end, we propose a simple evaluation criterion, NLL-QA, to replace the negative log likelihood (NLL) criterion universally employed in state-of-the-art neural question generation models to evaluate and select the final output question. Preliminary results demonstrate that, compared to the traditional negative log likelihood criterion, NLL-QA enables neural question generation models to select better questions that are more relevant to the input answer without sacrificing grammatical correctness.

1. INTRODUCTION

We focus on a particular class of neural question generation (NQG) models that takes as input *an answer* and *an answer context*, usually a sentence or paragraph containing relevant information about the answer, and aims to output *a question sentence*. These NQG models [3, 20, 19] are able to generate questions¹ of much higher quality than previous rule-based systems [5, 1, 8], demonstrating their potential in improving performances of machine comprehension and question answering tasks [18, 14, 4] as well as automating the generation of quiz questions in large-scale educational settings [10, 9]. The question generation process using a NQG model is as follows First, beam search samples a list of candidate questions from the model. Then, a post-processing step selects the most probable question according to the negative log likelihood scores (NLL) of the candidate questions as the final output question.

For a question generated in the above manner to be of practical value, it needs to be, at a minimum, free of grammatical errors and relevant to the input answer from which it is generated. Unfortunately, state-of-the-art neural question generation models often

¹In our context, *generate* a question is equivalent to *output* or *select* a question.

Zichao Wang "Techniques for Automatically Evaluating Machine-Authored Homework Questions" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 714 - 717

Context 1: It stands on the Vistula River in east-central Poland, *roughly 260 kilometres (160 mi) from the Baltic Sea and 300 kilometres (190 mi) from the Carpathian Mountains.*

Question 1: How long is the Vistula River in the Vistula River? (10.21)

Question 2: How far is the Vistula River from the Baltic Sea? (10.67)

Context 2: *For exercise*, Tesla walked between 8 to 10 miles per day.

Question 1: How did Tesla travel to 10 miles per day? (12.55)

Question 2: Tesla walked between 8 to 10 miles for what? (14.15)

Table 1: Two examples where the most probable question (Question 1, which is the final output selected by NLL) is unsatisfactory: in Context 1 it contains grammatical errors, and in Context 2 it asks a question irrelevant to the input answer (*italic and underlined text* in Context). In both examples, a less probable question (Question 2) is significantly better than Question 1. The raw negative log likelihood is shown after each question.

generate questions that do not satisfy these two desired properties. Interestingly, we have discovered, by manually examining numerous generated questions, that a less probable question is of much higher quality than the most probable one in a number of cases. To illustrate, Table 1 shows two less probable questions that are more fluent and more relevant to the input answers than the most probable ones. This observation suggests that, even though a satisfactory output question may already appear in the beam search results, the NLL criterion is often unable to select it.

Moreover, we notice that smart changes in the post-processing step, in addition to the model itself, can bring significant benefit in language generation tasks. For example, Google's neural machine translation system augments NLL with length and coverage penalties, considerably improving the BLEU score of the translations [17]. We are thus motivated to explore the possibility of improving the quality of generated questions by redesigning the question selection criterion in the post-processing step of the question generation process.

Contributions. We propose NLL-QA, a novel question selection criterion that combines NLL with a *answer relevance score (QA)* that explicitly evaluates whether a candidate question can be correctly answered by the input answer from which the question is generated. This combined score is then used in place of NLL to select the final output question from the candidate questions output by beam search. Intuitively, this selection criterion encourages the final output question to be relevant to the input answer, an important aspect of a good generated question that NLL fails to adequately evaluate.

We demonstrate via qualitative, quantitative, and human evaluations that NLL-QA selects questions that are more relevant to the input answers than those selected by NLL without sacrificing grammatical correctness. A further advantage of our proposed criterion is its versatility and ease of implementation. Since our criterion is used only in the post-processing step, it does not affect the NQG model itself in any way, and thus can be easily incorporated together with any advances in the NQG model to jointly improve the quality of generated questions. Our work therefore provides a new approach to boost performance of either existing or newly developed NQG models.

2. THE NLL-QA CRITERION

The proposed NLL-QA criterion calculates a composite score S for each candidate question as a convex combination of negative log likelihood and an answer relevance score QA:

$$S = \alpha \text{NLL} + (1 - \alpha) \text{QA}, \quad (1)$$

where $\alpha \in [0, 1]$ is a tunable hyper-parameter. Intuitively, α controls the relative importance of NLL and QA in selecting the final output question. We note that the case of $\alpha = 1$ corresponds to the usual NLL criterion. We have experimented with a range of α values and have observed that setting $\alpha = 0.3$ in Equation 1 worked well.

Answer Relevance Score. To calculate the answer relevance score, we first use a *question answering model* to answer the generated question. The question answering process takes as input a question and a context, and outputs a list of N predicted answers, with a confidence score in range $[0, 1]$ associated with each predicted answer. We then compare the answer predicted by the question answering model to the input answer from which the question is generated. Intuitively, if the question can be correctly answered, i.e., the input and predicted answers are identical or sufficiently similar, we would assign a high answer relevance score to that generated question.

Although automatic question answering is by itself a difficult task, recent question answering models have achieved performance almost on par with humans [2, 13, 15] on benchmark datasets such as SQuAD [12]. Question answering models thus provide a reasonable evaluation of answer relevance of a question without resorting to human evaluators. The answer relevance score QA is calculated as follows:

$$\text{QA} = \min_j (-\log(c_j \cdot \text{sim}(A, A'_j) + \epsilon)), \quad (2)$$

where A is the input answer from which the question is generated, A'_j is the question answering model predicted answer indexed by j , c_j is the confidence score associated with the j th predicted answer, and ϵ is a small number for numerical stability. The similarity function $\text{sim}(\cdot, \cdot)$ outputs a similarity score in range $[0, 1]$ by comparing the input answer to the j th predicted answer A'_j . We use the Ratcliff-Obershelp algorithm for the similarity function in our experiments, which effectively calculates the string similarity between the input and predicted answers.

3. EXPERIMENTS AND RESULTS

We now describe our experiments to evaluate the efficacy of our proposed NLL-QA criterion using qualitative, quantitative and human evaluation metrics.

Model and Dataset. To show the wide applicability of NLL-QA,

Context 1: The 2010 United States Census reported that Fresno had a population of 494,665.

Human: What was Fresno’s population in 2010?

NLL: What was the population of the 2010 United States Census?

Ours: What was the population of Fresno in 2010?

Context 2: In July 1968, ABC continued its acquisitions in the amusement parks sector with the opening of ABC Marine World in *Redwood City, California*; ...

Human: Where was ABC Marine World opened?

NLL: Where was ABC Marine World World World World World World World demolished ?

Ours: Where was the ABC Marine World sector located?

Context 3: The capability of the command module’s *heat shield* to survive a trans-lunar reentry was demonstrated by using the service module engine to ram it into the atmosphere at higher than the usual earth-orbital reentry speed.

Human: What was one thing that was specifically tested on the Apollo 4 test launch regarding the cm?

NLL: What led to the command module?

Ours: What did the command module provide to survive a trans-lunar reentry?

Context 4: *The sexual ethics task force of the United Methodist Church* states that “research shows it [pornography] is not an ‘innocent activity.’”

Human: Which task force states that pornography is harmful?

NLL: What states that “research shows it is an innocent activity”?

Ours: What states that “research shows it is not an innocent activity”?

Table 2: Representative questions selected by different criteria and human generated reference questions. The italic and underlined text in each context is the true answer. NLL+QA consistently selects higher quality questions than NLL.

we implement, test and compare it with NLL on two state-of-the-art NQG models: **LSTM + attention**, which is a sequence-to-sequence LSTM network with attention mechanism [3]² and **LSTM + attention + copy**, which is LSTM + attention model with additionally copy mechanism [20]. We train each model on the SQuAD dataset [12], each entry in which contains an answer, an answer context, and a human generated reference question. During evaluation, for each entry in the SQuAD test set, beam search first samples 10 candidate questions from the chosen NQG model. Then, the two criteria, NLL-QA and NLL, respectively select a top question out of the 10 candidates as the final output.

We use a trained DrQA model [2] to output predicted answers for Equation 2.

Qualitative Evaluation. For illustration purpose, Table 2 shows representative examples where NLL and NLL-QA return different questions and compare them side-by-side, using LSTM + attention + copy model.³ This allows to observe general differences in performance for these two criteria. It is clear that our combined criterion selects higher quality questions. For example, in Context 2, NLL selects a question that repeats the word “World”, while NLL-QA selects a question that is grammatically correct. In Context 4, both questions are fluent, but NLL selects the question without the crucial negating word “not”, which makes the question inappropriate. On the contrary, NLL-QA correctly selects the question with the appropriate negation.

²To be precise, we modified the implementation of [3] so that it can take the answer word(s) as input.

³In our experiments, NLL+QA selects the same questions as NLL in 38.6% of all tests.

NQG Model	Selection criterion	Metrics					
		BLEU-1	BLEU-2	BLEU-3	BLEU-4	METEOR	ROUGE-L
LSTM + attention	NLL	0.4216	0.2603	0.1797	0.1284	0.1702	0.4212
	NLL-QA	0.4340	0.2684	0.1850	0.1323	0.1766	0.4180
LSTM + attention + copy	NLL	0.4583	0.3030	0.2216	0.1684	0.2035	0.4596
	NLL-QA	0.4661	0.3038	0.2190	0.1637	0.2049	0.4572

Table 3: A comparison between questions selected by NLL and NLL-QA, with the higher scores bold. NLL-QA selects questions of comparable or slightly higher quality for all metrics for both NQG models.

(a) Results for LSTM + attention model.

(b) Results for LSTM + attention + copy model.

Figure 1: Graphical summary of human evaluation results. “Ties” means that raters choose the same preference for both questions, e.g., when raters think both NLL and NLL-QA selected questions are grammatical. NLL-QA dominates in answer relevance and in overall preference. Best viewed in color.

Automatic Evaluation. Similar to prior works [3, 20], we include evaluation results using an array of common automatic metrics including BLEU [11], METEOR [6], and ROUGE [7]. Table 3 summarizes these evaluation results, with the best criterion in bold, for both NQG models. Results in Table 3 show that, overall, NLL-QA selects questions that are of comparable or even slightly higher quality than those selected by NLL. We emphasize that the above evaluation metrics are *not* the most appropriate ones for evaluating the quality of questions, which motivates the human evaluation experiments that we now describe.

Human Evaluation To verify that NLL-QA indeed outputs questions of higher quality than NLL, we conduct a human evaluation experiment for each NQG model. We randomly sample 150 entries from the SQuAD test set where NLL and NLL-QA criteria return different results. For each NQG model, and for each pair of questions, we ask six human raters to give three categories of preferences, one based on grammatical correctness, one on relevance to input answer, and one on overall preference.

We then count the number of times each criterion the raters chose for each of the three preference categories. Figure 1 presents these results graphically for both NQG models. Comparing the last two bars in each plot, we see that, overall, human raters prefer NLL-QA twice as often as NLL. Comparing answer relevance in each plot, we see that human raters strongly prefer NLL-QA than NLL. We performed binomial tests confirm the significance of these two observations: $p = 6.8 \times 10^{-4}$ and $p < 10^{-4}$ for overall preference, and $p = 1.5 \times 10^{-11}$ and $p = 0.01$ for answer relevance, for LSTM + attention and LSTM + attention + copy model, respectively. Comparing grammatical correctness in each plot, there seems to be a slight preference for NLL over NLL-QA. However,

binomial test shows that this slight preference is not statistically significant at all, with $p = 1$ for LSTM + attention model and $p = 0.75$ for LSTM + attention + copy model.⁴ We thus conclude that NLL-QA significantly outperforms NLL on both answer relevance and overall quality without sacrificing grammatical correctness.

4. CONCLUSIONS AND FUTURE WORK

We have introduced NLL-QA, a simple yet effective criterion to replace the traditionally used NLL criterion in the post-processing step during the question generation process using neural question generation models. Through various evaluations, we have shown the promise of NLL-QA in improving neural question generation performance without changing or fine-tuning the question generation model itself.

The major challenge is defining a proper metric to evaluate the generated questions. NLL-QA is as reasonable criterion if we our metrics are grammatical correctness and relevancy to the input text. These two metrics are obviously unsatisfactory in educational domain because we also care about the “educational value” of a generated question, which is difficult to quantify, let alone doing so automatically. Therefore, I would like to discuss ways to define quantitative metrics for evaluating questions and methods to do so automatically.

Beyond Autoscoring: Extracting Conceptual Connections from Essays for Classroom Instruction

ABSTRACT

While automated essay evaluation techniques have dramatically reduced instructors' grading burden, they fall short of providing instructors with the rich qualitative insights into students' sense making process that a careful read of essays can afford. In this study, we demonstrate how word embedding techniques can serve as a complement to automated scoring, providing instructors with valuable near-time insight into how their students are conceptualizing targeted lesson concepts. For this study, we use a post-test essay associated with two Web-based Inquiry Science Environment (WISE) units that provides instruction about how the sun causes increases in temperature. We create word2vec models fit to students' c-rater scored essay responses at each score level of a rubric designed to assess students' integrated understanding of targeted concepts. Using cosine similarity, we identify, with statistically reliability, the ideas that students at each score level of the rubric used in relation to the concepts targeted in the essay prompt. Our instructor interview reveals the validity of the results in providing insight into students' ideas, differentiated across understanding levels.

1. INTRODUCTION

In the domain of science, new science education reform efforts, like the Next Generation Science Standards (NGSS), call for students to both coherently understand and communicate complex science ideas[6]. Consequently, essays that assess students' developing knowledge of complex science ideas could increase the validity of assessment in science classrooms[6]. Concomitant with the call for increased use of essay assessments is the need for machine-based techniques to quickly and reliably analyze student essays in order to provide instructors with qualitative insights about how their students are developing and connecting complex science concepts.

Advances in the field of natural language processing (NLP) have given rise to automated essay evaluation (AEE) tech-

niques that help instructors meet the challenges of essay scoring. However, there is still the need to develop effective techniques to assess and support students' comprehension of complex ideas expressed in their essays[9]. In order for instructors to provide targeted support based on their students' developing ideas, they need to have the qualitative insight that comes from reading the essays. Without it, instructors are left in the dark regarding the different ways their students make sense of the targeted concepts being assessed by the essay item. Even though instructors may have access to the exemplars used to train AEE models, the distance between the exemplar responses and that of their students can leave instructors guessing about the true nature and quality of their students' understanding. In this study, we describe the development and evaluation of word2vec models that augment the value of automated scoring by analyzing and comparing the conceptual connections that students in different scoring categories express in their essay.

2. BACKGROUND

Research in the field of teaching and learning has shown students' ability to develop an integrated understanding of complex ideas, such energy transfer and transformation, is influenced by how well their instructors notice and understand their ideas[8]. Therefore, to support students in communicating integrated understanding of complex ideas, it is important to develop machine-based analyses that provide teachers opportunities to see, understand, and respond to student ideas.

2.1 Auto-scored Student Essays

In partnership with Educational Testing Services (ETS), we have previously used the c-rater algorithm to score student essays from various assessment items in Web-based Inquiry Science Environment (WISE) units[2]. The student responses used to train the c-rater model were human-coded using a rubric based on the Knowledge Integration (KI) framework[4]. The KI framework supports students to sort through their ideas to develop an integrated understanding of normative science concepts[3]. Since the rubric used to score the essay assessment items in the units prioritizes the links that students make between normative science ideas, the c-rater generated scores reflect the extent to which students' ideas are normative and linked.

To support instruction based on students' ideas, we create skip-gram models[5] of students' c-rater-scored essay re-

sponses. In doing so, we were able to augment automated essay feedback and, thus, provide instructors with quantitative information regarding the correctness of students' ideas and qualitative information regarding the connectedness of their ideas.

2.2 Science Content Knowledge

The WISE units used in this study were designed to support students in developing an integrated understanding of how energy from the sun is transferred and transformed and how those processes cause an increase in temperature. To develop a normative and integrated understanding of this complex concept, students need to link the following ideas:

- Energy from the sun travels to Earth in the form of solar radiation.
- Solar radiation is in part reflected and absorbed by objects.
- Once absorbed, solar radiation is transformed into heat energy, resulting in an increase in temperature.
- Objects that absorb solar radiation can re-emit that energy in the form of infrared radiation.
- Infrared radiation is blocked and reflected by certain objects (e.g. atmospheric gasses, glass).
- Like solar radiation, infrared radiation is in part reflected and absorbed by objects.
- Once absorbed, infrared radiation is transformed into heat energy, resulting in an increase in temperature.

The assumption is that students at each score level conceptualize and connect these science ideas differently. Since the word2vec models encode the semantic meaning of the words as vectors, we can, for example, analyze the differentiated ways students scoring at the level of 2 conceptualize "temperature" as compared to how students at a level 5 conceptualize "temperature". Using cosine similarity, we can provide teachers with a list of the words that their students have conceptually connected to the target lesson concept (e.g. temperature).

Given this potential, we conducted this study to address the following research questions:

1. Can we develop a skip-gram model from pre-scored essay responses to reliably extract the differential ways students develop and conceptually connect complex science ideas?
2. Do the skip-gram models generate results that are pedagogically informative (i.e. support teachers to notice, understanding, and respond to their students ideas)?

3. METHODOLOGY

3.1 Offline Model Development (RQ1)

Student essay responses were prepared for skip-gram development using standard Python libraries, pywsd and NLTK were used to perform basic NLP techniques (i.e. case-adjustment,

abbreviation expansion, punctuation and symbol exclusion, lemmatization, and stopword modification and removal)[1]. Skip-gram models for student responses at the KI rubric score levels (range 2-5, four total) were developed using the gensim library[7]. Model hyperparameters were adjusted to produce cosine similarity results to the various target words that a content-expert validated as conceptually relevant to the prompt. To extract the meaning of a word as used and understood by the student rather than its conventional meaning, we created the word vectors from the study datasets rather than using pre-trained vectors.

3.2 Classroom Evaluation (RQ2)

To determine the efficacy and utility of our skip-gram models to support teacher noticing of student ideas, we conducted a semi-structured interview of the high-school physics instructor whose students' essay responses generated the model results referenced during the interview.

3.3 Datasets

The dataset used in the offline development and evaluation of the skip-gram models consisted of student text responses to the explanation portion of the following post-test essay assessment item:

Let's think about how global warming happens. On a COLD day, Akbar walks to his car that is parked in the sun and has not been driven for a week. Predict the temperature inside the car:

- Colder than the outside air
- Warmer than the outside air
- Exactly the same as the outside air

Explain your answer:

The students of four sixth grade science teachers from two Bay Area middle schools (N=497) generated their responses to this prompt after engaging the WISE Global Climate Change unit (<https://wise.berkeley.edu/project/24751>). In this unit, students learned how solar radiation from the sun can be absorbed, transformed into heat energy, and trapped by greenhouse gases as infrared radiation, which leads to increased temperature.

Student responses were, on average, 34 words long and were human-coded, from 1 (low) to 5 (high), using a KI rubric. Responses received a score of 1 if they were off-task or irrelevant and, thus, were excluded from the model development dataset. Responses that included normative but unconnected ideas about the transformation of solar radiation to heat received a score of 3. Responses that connected one or more normative ideas about the transformation of solar radiation to heat received a score of 4 or 5, respectively. The distribution of scores were as follows: Score 2 = 243; Score 3 = 92; Score 4 = 42; Score 5 = 23.

The dataset used in the classroom evaluation of the skip-gram models consisted of student text responses to the same essay prompt used for the offline model development and evaluation (see above). The students of a ninth grade physics

Table 1: The cosine similarity results for the target word "temperature" of the skip-gram models associated with each score level using the development dataset. The vocabulary size of each model is in parentheses.

Temperature							
Score = 2 (105)	cos_sim	Score = 3 (55)	cos_sim	Score = 4 (62)	cos_sim	Score = 5 (58)	cos_sim
become	0.999	get	0.998	inside	0.985	get	0.987
reason	0.999	into	0.994	get	0.985	glass	0.981
colder	0.999	become	0.987	glass	0.981	inside	0.981
inside	0.999	glass	0.986	into	0.969	become	0.976
time	0.996	inside	0.977	become	0.968	into	0.961
get	0.995	particle	0.967	travel	0.967	car	0.935
hot	0.995	may	0.933	radiation	0.955	bounce	0.906
warmer	0.993	bounce	0.932	bounce	0.922	pass	0.87

Table 2: The most similar words and associated p-values for the target word "heat" of the skip-gram models associated with each score level using the development dataset. The vocabulary size of each model is in parentheses.

Heat							
Score = 2 (105)	p-value	Score = 3 (55)	p-value	Score = 4 (62)	p-value	Score = 5 (58)	p-value
outside	<1.0E-6	outside	2.42E-04	car	1.13E-04	car	0.009
inside	<1.0E-6	inside	0.012	air	0.007	glass	0.009
temperature	<1.0E-6	air	0.049	glass	0.045	infrared	0.009
cold	<1.0E-6	energy	0.049	radiation	0.045	energy	0.042
air	<1.0E-6	get	0.049	turn	0.045	day	0.042
warm	<1.0E-6	into	0.049			light	0.042
get	3.58E-06	warm	0.049			solar	0.042
sun	0.039	trap	0.049				

instructor from a Bay Area high school generated their responses (N=155) before and after engaging the WISE Solar Ovens unit, which focused on designing, building, and testing a solar oven (<https://wise.berkeley.edu/project/24537>). In this unit, students learned about the same energy cycle described in the sixth grade unit, and then explored how different designs influence that energy cycle and temperature change in a solar oven.

Student responses were, on average, 30 words long and were scored using a c-rater algorithm based on the same KI rubric used for the model development dataset. Similarly, responses received a score of 1 if they were off-task or irrelevant and were excluded from the dataset. The distribution of scores were as follows: Score 2 = 82; Score 3 = 46; Score 4 = 22; Score 5 = 3. Due to sparseness of responses at the score level 5, a skip-gram model was not created for this score level.

4. RESULTS

4.1 Offline Model Development (RQ1)

We chose "heat" and "temperature" as target words for our model evaluation, since the essay used in this study was designed to assess students understanding of how solar radiation and infrared radiation cause an increase in temperature. Our initial cosine similarity results from the four skip-gram models appeared to be consistent with our content expert's expectations regarding the ways that students are different scoring levels would connect ideas related to "temperature" (see Table 1). However, these initial results were not reproducible from one model run to the next, in terms of exact words and relative cosine similarity rank. The top 8 results for each model within a given run displayed patterns con-

sistent with the content expert's expectations, albeit with variable reproducibility.

We used distribution probability to establish the statistical reliability of our model results. Specifically, we used hypergeometric and binomial distribution test, respectively, to determine the probability that any given word in the model's vocabulary would appear in the top 8 cosine similarity results and do so consistently enough to yield a p-value < 0.05. We ran each model 12 consecutive times on a random sample of the essay responses, where the number of responses in the sample equaled the total number of responses in the dataset. After 12 consecutive runs of each model, words would need to appear in the top 8 cosine similarity results of 3 or 4 of the runs, depending on the model's vocabulary size, to achieve a p-value < 0.05 according to the reliability test.

Using the development dataset, we generated a statistically reliable list of the words based on the model results for the target word "heat" (see Table 2). Examination of this list revealed conceptually meaningful differences across the scoring levels, as confirmed by the content expert and physics instructor. The most statistically reliable results using the target word "heat" were: score level 2 model: air, temperature, inside; score level 3 model: inside, energy, trap; score level 4 model: car, air, radiation; and score level 5 model: car, radiation, trap (see Table 2). These model results indicate a typical progression of student ideas when they are beginning to understand the mechanism of how solar radiation transforms to heat.

Table 3: The most similar words for the target word "temperature" of the skip-gram models associated with each score level using the classroom dataset. The vocabulary size of each model is in parentheses.

Temperature		
Score = 2 (92)	Score = 3 (68)	Score = 4 (62)
become	get	inside
reason	into	get
colder	become	glass
inside	glass	into
time	inside	become
get	particle	travel
hot	may	radiation
warmer	bounce	bounce

That the lists of words produced from the target word "temperature" are similar to those from the target word "heat" reflects the similar ways in which students conceptualize "temperature" and "heat".

4.2 Classroom Evaluation (RQ2)

To investigate the alignment of the model results with the instructor's expectations of the conceptual connections that students at each score level would make, we presented the instructor with the cosine similarity results from each model for the target word "temperature" (see Table 3). Although the statistical reliability for the model results had not yet been established, we asked the instructor to interpret the results for each individual model and cross-comparatively. The instructor commented that the results from the model resonated with her expectations of what a developed understanding looks like and what a still-developing understanding looks like.

Furthermore, we asked the instructor when and she might use the information provided by our models. She indicated that she would use a tool like this as a form of formative assessment to see what her students' ideas were while instruction was still ongoing. She went on to say that she could use the information from the models to inform her instruction, and that it would help her to decide if she needed to have a whole class conversation, do a demo, or show a video to support her students in sorting and integrating their ideas towards normative understandings.

5. SUMMARY AND ADVICE SOUGHT

Our ability to create meaningful embedding models of the differentiated way students at each scoring level conceptualize target ideas has several implications:

- A strategy for extracting statistically reliable and meaningful results from small, unevenly distributed datasets typical of K-12 classrooms and upper-division college courses
- The revelation of subpopulation-specific conceptualizations of target lesson concepts
- The realization of the full assessment power of essays in an online learning environment

For this doctoral consortium, I would like advice regarding how to further validate my models. Since my approach utilizes relatively small datasets to generate instructor/class-specific results, I would like to discuss additional ways to establish the reliability of my model results. Beyond distribution probability, what other statistical methods could I use to establish reliability? Which other approaches would serve as comparison cases for further model evaluation? Furthermore, to which other domains should we apply our model?

A major factor to consider in the consortium discussion is what instructors have identified as a barrier for use, namely model understandability. Instructors with whom we partner have stressed the importance of being able to understand how the models that automatically assess student responses work. Importantly, their confidence in the model results is linked to the extent to which they understand how the model generates the results. Therefore, it is a priority to develop a model that both generates meaningful results and can be easily explained.

Our results are promising and, through this consortium, we hope to determine how best to further develop our approach for essay evaluation so that both researchers and practitioners can be confident in the results.

Predicting student academic outcomes in UK secondary phase education: an architecture for machine learning and user interaction

Matthew Woodruff
Department of Computer Science
University of Surrey
Guildford, Surrey, UK.

m.woodruff@surrey.ac.uk

ABSTRACT

Groups of schools face significant challenge to ensure that student assessment is consistent and valid, that predictions are accurate and that data policy does not adversely impact teacher workload. This study looked to determine if student outcomes at the end of secondary phase education in the UK, and by extension elsewhere in the world, could be reliably predicted. Data from two academic years, twenty-three secondary schools representing cohorts of approximately four thousand students were used to conduct comparative analysis on multiple machine learning experiments utilising Microsoft Azure Machine Learning and code written in Python. Findings indicate that Attainment 8, the main performance indicator used by the UK Department for Education, could be predicted by linear regression models and neural network approaches with an accuracy in line with human (teacher) predictions, and when combined with human predictions the models provided significant ($P=0.00039$) gains on either approach in isolation. Seeking advice on further research particularly to introduce interactions to include a 'human in the loop' on model inputs, to refine feature selection, and to predict curriculum level variations in order for human intervention to occur early and improve outcomes.

Keywords

Predictive analytics, Machine Learning, Student outcomes, Python, Azure, Bot, human in the loop.

1. INTRODUCTION

'Progress 8' is an important measure in the current accountability framework for secondary phase state funded education in the UK [1]. Many countries have similar national tests, such as the National Assessment of Educational Progress (NAEP) in the US or the NAPLAN tests in Australia [2]. In brief, it measures the progress a student makes in academic study across their best eight subjects. It measures this from their attainment at point of exit from primary phase education (aged 12 / National Curriculum Year 6), and its basis is relative to average attainment of the prior year's cohort (at age 16 / National Curriculum Year 11), from the same starting

point. Progress 8 is used both at a student level, and aggregated in average to provide a 'score' at an institution level. A score of 0 represents a student (or school) making the average progress for students of the same prior attainment in the prior year's cohort. A score of 1 would represent that the student has made on average one grade more progress in each of their subjects (and conversely, -1 meaning one grade less progress).

Progress 8, in and of itself, is of limited use for formative or summative assessment at a student or school level. The data from which it is derived would be more appropriate for these purposes, namely subject level concept understanding, application and progression. Despite the inherent difficulties in reliably predicting Progress 8 [3], it is common place for schools to do so. In part, this is due to its nature as a high-stakes key performance indicator – one upon which the quality of education provided by the school is judged. Education policy in recent years in the UK has driven schools to become part of Multi Academy Trusts (MATs), and 72% of secondary phase education is now delivered by schools with Academy status [4], and part of a MAT.

The study involved a large MAT with a geographical spread and accountable for schools in all phases in both the state and the independent sectors. In 2018 the MAT formed a project partnership with Microsoft and Coscole, a specialist company focusing on education data and analytics. In addressing the need to predict Progress 8 and therefore understand how and where to intervene to support its students, the MAT surmised:

- The methods adopted for teacher led subject predictions are variable across schools, and within them
- Historical variance between teacher predicted outcomes and actual outcomes have not been easy to explain
- Significant time can be spent by staff, leadership teams and trusts in the production and analysis of data relating to likely outcomes
- Patterns of human predictive accuracy were not consistent between academic years

Given these challenges two key questions were posed:

- Can machine learning methods achieve human like predictive capability (or better) for Progress 8?
- If so, could the administrative burden placed on schools in the production of these metrics be reduced?

Matthew Woodruff "Predicting student academic outcomes in UK secondary phase education: an architecture for machine learning and user interaction" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 722 - 725

2. METHODS

If the results of this study were favourable in terms of predictive accuracy of outcomes it would be important to the study participants that there would be a mechanism for the approach to be repeatable, and to scale. A solution architecture was therefore identified at the outset that would support both of these considerations. The study comprised of data from 23 secondary schools, with a population of over 4000 students in their final year of study (National Curriculum Year 11, age 16).

2.1 Solution components

Figure 1 shows the high-level design that was created to support the modelling process and a proof of concept (POC) environment.

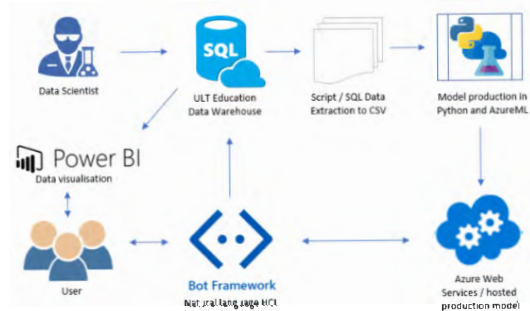

Figure 1. Proof of concept high level design.

2.1.1 Human computer interaction

The requirement for the human-computer interaction was to ensure that the supply of data, and the return of predictive output could be transacted by an education practitioner with little technical expertise. We identified existing channels in the MAT environment (and common in many MATs) for this interaction to occur and provided a ‘Chat Bot’ style interface in order to achieve the transfer of data, machine learning orchestration and for the supply of information back to the user. An overview of this process can be seen in Figure 2, below.

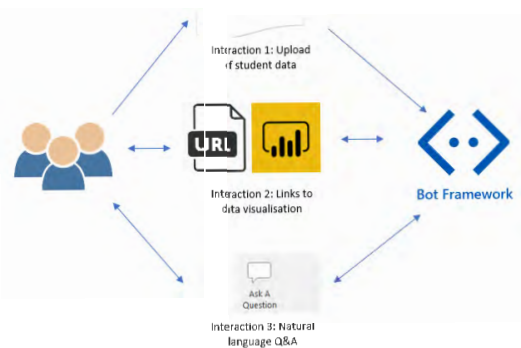

Figure 2. Human computer interaction POC scenario.

This interaction outputs predictive data to table outputs in Microsoft SQL Azure, which can be consumed by the Bot framework and/or by the data visualisation layer.

2.1.2 Data visualisation

In addition to the supply of predictive output back to the practitioner by way of the Bot interaction, in depth data visualisation was provided by Microsoft Power BI. When the machine learning predictive experiment web service completes, the resulting predictive data is posted to an Azure database table. Reports were created for data visualisation that consumed data from this table. The user could either navigate to the Power BI workspace where the report resides, or follow a link that that Bot posts to the chat window (should the session still be active). The link may include the refreshing of the report content, ensuring that the view of the data is always current.

3. Model features

3.1 Student characteristics

Common student characteristics exist that form the basis of much analysis completed in this sector. The annual government league tables, and other information that is available publicly, includes dimensions on gender, ethnic origin, prior attainment, ‘pupil premium’ where additional government funding is given due to disadvantage, and special educational needs. Given a body of research drawing correlations between these characteristics and educational attainment [5] they were included in the model features.

Student characteristics were converted into Boolean form (for example ‘Is Male’, ‘Is Special Educational Needs’, or ‘Is White British’)

3.2 English and Maths ‘Mock’ examination results

The MAT has a standard curriculum for ‘Mock’ examinations taken by Year 11 student in their final year of study. We could therefore use 2016/2017 exam data as a feature input as data on the same basis would be available for 2017/2018. This data is an integer scale (1-9), and also was likely to be correlated to the Progress 8 outcome (as Progress 8 double weights English and Maths). Other English and Maths data was available; however, it was excluded from our feature selection as it formed compound measures on the grade.

3.3 Prior attainment

Logic suggests that a student’s prior academic performance would be a good indicator of their future academic performance, a conclusion that is well supported by evidence [5]. Prior attainment data was available in the form of the student’s average attainment from the end of primary phase education (their ‘Key Stage 2 Average Fine Level’).

3.4 Teacher predictions

Data was available at student level with a teacher’s prediction of ‘likely’ grade at a subject level (for example in English Language, Mathematics, History and so on). Initially this feature, as a composite measure ‘Teacher Predicted Attainment 8’ was withheld from the machine learning experiment, and later introduced for comparative purposes.

4. Machine learning

4.1 Azure Machine Learning

Azure Machine Learning Studio was used to build several iterations of experiments. It was used to:

- Conduct feature analysis to understand which components of our data were most significantly correlated to the target (Attainment 8). This was performed by the Filter Based Feature Selection module using Pearson's correlation method, following the test/train split.
- Understand which forms of regression algorithm would be best suited to the type of predictive output
- Tune the resulting model hyperparameters for the smallest error

The final experiment utilised the Boosted Decision Tree Regression to create an ensemble of regression trees using boosting (where each tree is dependent on prior trees). This algorithm learns by fitting the residual of the trees that preceded it. The Azure ML implementation uses the Multiple Additive Regression Trees (MART) gradient decent boosting algorithm [6]. The filter-based feature selection module was used during the initial experiment. However, this was not necessary using the boosted decision tree algorithm due to its internally created feature summary (whereby features with zero weights are not used by any tree splits).

During the experiment the Azure ML function 'Tune Model Hyperparameters' was used and the results set to the recommendation of 25 leaves per tree, 25 samples per leaf node, a learning rate of 0.167076 and a total number of 125 trees were constructed.

4.2 Python

In addition to the Azure ML experiments a Python model was built as a comparative approach. This was completed not as a direct methods comparison, but as an illustration of the capability for Azure ML to host Python scripts within its data flow, and therefore to have complete control over all model features.

Initially, a Neural Network was used in the Python implementation and simplified to input (64 nodes), output and a single hidden layer (64 nodes). Its optimiser was set to use the RMS Prop Optimiser [7] and its learning rate set to 0.001.

When the validation error was no longer reducing over a defined number of epochs (20), we stopped the training.

Following this, a number of comparative algorithms were used which included a decision tree, a boosted decisions tree, a 2-layer neural network and a linear regression. In addition to the variation in algorithms, the experiments were modified to include or exclude 'Teacher prediction' data from the model, and also to extend the feature set to include further data related to the English and Maths results. The Python experiments were written in a VSCode environment using the Anaconda 3.0 deployment.

5. Results

It was realised early in the study, following unpredictable model outputs, that directly predicting Progress 8 was not going to be successful. It is beyond the scope of this paper to explain in depth the Progress 8 definition, but in summary it is a compound measure that utilises 'Attainment 8' (the eight highest grade values) and then applies a conversion based on the student's prior attainment and last year's cohort average attainment to result in a decimal number distributed around zero.

Instead, it was determined that Progress 8 may be predicted by predicting the Attainment 8 score, and then applying the known conversion method ([1], p27) to convert to the Progress 8 score.

The root mean squared errors (RMSE) of eight algorithmic approaches are compared to the RMSE of the teacher (Human)

prediction in Figure 3. Here we can see that both of the Neural Network approaches, as well as the Linear Regression surpass the accuracy of the human prediction. Attainment 8 is a decimal in the range 0-88 (8 qualifications on a 0-9 scale) and an RMSE of 1 would represent 1 grade difference in total between predicted and actual achievement.

Figure 3. Root Mean Squared Errors of Python algorithms.

An F-Test was performed on the sample variance of the teacher prediction and the linear regression results to determine that the variances of the populations were unequal. A subsequent T-Test was conducted with the conclusion that the observed difference between the sample means is convincing enough to say that the average Attainment 8 result differs significantly ($p=0.000387$).

6. Discussion

This study set out to address two questions; Can machine learning methods achieve human like predictive capability (or better) for Progress 8, and if so, could the administrative burden placed on schools in the production of these metrics be reduced?

Initial findings suggest that machine learning approaches can produce output that is as reliable as human prediction. It could be argued that the time spent in collating such data, performing the analysis and communicating results can be reduced, therefore freeing time for education practitioners to focus their efforts in teaching young people and leading schools rather than wrangling data. However, in order to accomplish this at scale, system improvements would be required in terms of the automation of data collection, standardisation of assessment approaches, and in the human computer interaction to explain the meaning of results.

6.1 Human in the loop

We specified and delivered an architecture for data to be supplied by end users (defined by low technical, low data science knowledge), and the results to be understood by those users. We delivered this via a Bot Framework interaction for the upload of data and process trigger, and via data visualisation in Microsoft Power BI. We also included human input in the form of teacher predictions at a subject level.

We have not in this iteration, however, placed the human inside the feedback loop of the machine learning itself. There are opportunities to explore the following interactions. First, in data validation. Quality and clarity of data in educational settings, especially at an aggregated level, pose a significant challenge and our experiments eliminated data during the cleansing activity. Human input during this process may significantly improve the training data and help to reduce bias. The architecture could be extended to interact with the human to either input missing data, identify the correct rule-based approaches (for example where no prior attainment is available due to new entry into the UK state-based system) or to modify the feature weights (for example around the impact of disadvantage or ‘Pupil Premium’ at an individual level).

Second, what the human ‘knows’. Teacher interaction with students on a daily basis gives rise to a more complex understanding based on situational awareness and factors of data that are not easily captured formally. This might relate to wellbeing considerations, safeguarding and behaviours that are outside of the scope of data capture within the school.

Finally, although this is far from an exhaustive list, we could give more consideration to who the human is in this scenario. Obtaining data from students themselves, and on an ongoing basis, could trigger revisions to the predictive output.

6.2 Generalisability, bias, ‘explainability’, and ethics

The machine learning models in this study relied on a standard assessment practice in English and Maths mock exams, taken by all schools, with the same curriculum, at a similar time in the year, over two years (one for the training dataset and one for the test). It is not common for this structure to be in place, and so issues exist in how one might scale the predictive capability to other institutions and student populations. Many institutions utilise ‘Standardised Assessment’ practices in the Primary phase and Key stage 3 (age 11-14) using third party tests which to some extent addresses this issue, but these are rarely in place during Key Stage 4 (the focus of this study). There is a compelling reason to consider a longitudinal study on relative performance measures and other features that do remain consistent across schools.

For similar reasons we need to consider bias that may have been introduced in our model due to feature selection and the data cleansing activities. Notable examples exist where records may have been removed from training due to absent values, such as prior attainment. Prior attainment may be absent where a student has entered secondary state education either from private schools, from abroad, or in the case where parental consent was not given for the student to sit Primary exams. These characteristics of students might actually prove significantly correlated to outcomes, and bias may have been introduced in the way the training data was managed.

The algorithms used, and the HCI enabled is unable to provide the practitioner with an explanation of why a certain progress 8 score has been predicted at the level it has. This is important if machine output is to influence a decision on how public money might be spent to intervene to improve outcomes on its recommendation. It is recommended at a minimum that we include in the bot interaction or data visualisation confirmation of the weights we have applied to features in the regression, and have these communicated in a manner which can be understood. Further research is required to

understand how we might better describe, in human understandable terms, what path the machine has trod to reach its conclusions.

This leads fundamentally to our ethical considerations in predicting events that might lead a human to make a judgement on a student, and therefore tailor their educational experience in one direction or another. In an environment where all resources are scarce (notably funding) should a prediction be overstated, this might lead to a withdrawal of resources that would benefit the student and vice versa. The subjects must be aware of the manner in which data collected about them will be used, and it must be used in a way that supports the human decision-making process; it is not a replacement for it.

6.3 Impact to practitioners

We have identified, subject to certain challenges to be overcome with regard to standardisation and data collection, that a machine learning approach could provide additional predictive support and reduce workload. The next question is to what extent is this useful to practitioners to improve outcomes? The answer in this case is that it is at the very beginning of a series of activities that would prove more valuable for this purpose. As mastery of curriculum is broken down into subjects, the next level is to understand for those students that are predicted to miss their potential overall, which subjects in that composite measure are most at risk? Beyond P8 lies a cascading set of objectives to understand; which subjects are likely to have the furthest variance from expected standard? Which topics within those subjects? Which foundation principles need reinforcement?

ABSTRACT

Schools across the United States suffer from low on-time graduation rates. Targeted interventions help at-risk students meet graduation requirements in a timely manner, but identifying these students takes time and practice, as warning signs are often context-specific and reflected in a combination of attendance, social, and academic signals scattered across data sources. Extremely high caseloads for counselors compound the problem. At Infinite Campus, a large student information system provider, we modeled statistical relationships between student educational records and enrollment outcomes, using de-identified records and in-system analysis to guarantee student data privacy. The resulting risk scores are highly predictive, context-sensitive, nationally available, integrated into the existing student information system, and updated daily.

1. INTRODUCTION

Approximately 15% of American students do not graduate high school on time [16]. States and districts frequently employ interventions designed to improve educational outcomes, including reducing dropout rates. A key role of school counselors is to direct the application of these interventions to the students who need them most. Counselors first need to identify these students but are faced with information overload. Each student's data is distributed across a student information system (SIS) and often other systems or people, making it difficult to synthesize into an accurate, comprehensive portrait of a student's risk. Compounding the problem are extremely large counselor caseloads—the national average is 430 students per counselor—with higher numbers typical in schools serving children with other structural disadvantages [11].

Early warning systems function as “automated attention” for overworked counselors by automatically identifying students

who might benefit from additional institutional resources. They automate the more tedious data analysis and summarization tasks so that counselors can focus on what humans do best: building relationships.

1.1 Alternate approaches

An effective dropout prevention system requires developing people, processes, and technology [7], identifying valid predictors, managing data and reports, assigning interventions, and monitoring student progress [10, 15]. In this paper, we focus just on the technology that identifies risk factors and estimates student dropout risk, which can then be embedded in a larger dropout prevention system.

Quantitative and qualitative determination of school dropout risk factors is a decades-old area of research [19], though the mid-2000s were a particularly important inflection point. High-profile studies of dropouts in the Chicago [3] and Philadelphia [17] urban districts led to the development of statistical methods for determining risk factors and their incorporation into early warning systems. Several organizations, often working together, have been instrumental in encouraging American schools to adopt research-based best practices [10], including the U.S. Department of Education's Regional Education Laboratories [18], the Consortium on School Research [2] and NORC [7] at the University of Chicago, the American Institutes for Research [8], and the Everyone Graduates Center at Johns Hopkins University [9]. Most states now make an early warning system available to their school districts [6].

Until the mid-2010s, all widely-used dropout early warning systems used threshold-based models, characterized by a few easily comprehensible predictors with associated risk thresholds (e.g., failing at least one course or being absent at least 20 days). The simplicity and auditability of these models, and the associated ease of implementation using common software and spreadsheet skills, is their key advantage over machine-learned systems. Students are measured on each predictor and flagged as “on-track” or “off-track” based on which side of a preset threshold their data point falls. Staff can intervene with students who have the most “off-track” risk flags, or whose risk areas correlate with particular intervention domains. A particularly influential approach is Balfanz's “ABC” taxonomy, in which students are measured on attendance, behavior, and course performance metrics [4], optionally with different thresholds for different student subpopulations [12]. While some educational institutions

*Infinite Campus, Blaine, Minnesota, USA

†@infinitecampus.com

implemented an ABC-style system themselves [10], others used spreadsheets or data tools made available by organizations like American Institutes for Research [8]. An active area of research involves determining which predictors and thresholds are appropriate for each school, or whether single thresholds are appropriate at all.

To overcome the limitations inherent in threshold-based systems, we and other organizations created machine-learned dropout risk identification systems in the mid-2010s. A number of researchers describe their systems in the academic literature (e.g., [1]) or industry white papers (e.g., [20]). Several organizations serve machine-learned dropout predictions at the scale of hundreds of thousands of students in many school districts. The Wisconsin Department of Public Instruction’s Dropout Early Warning System uses data reported to the state every few months by the districts’ SISs to build machine-learned models. The system produces two predictions per year and is available for students in grades 6–9 [14]. Mazin Education (through BrightBytes) and Hoonuit both sell machine-learned early warning and intervention monitoring systems for all grade levels.

Machine-learned systems have two major advantages over threshold-based models. First, the additional model complexity affords more accurate predictions and allows system designers to infer which risk factors are predictive in the presence of other factors or for different populations. Second, the variety of model architectures allows for more than just inferring overall risk. Designers can choose, for instance, to model time until dropout so that staff can intervene according to acuteness of risk, or to model uncertainty.

1.2 Our contribution

Two key obstacles prevent machine-learned early warning systems from being deployed nationwide. First, the predictive quality of these models is chiefly a function of data availability, as models must be trained on a large dataset—including a variety of educational contexts and outcomes—to ensure they perform well for students they haven’t seen before. Models built on a single district’s or even state’s data may not generalize well to other populations. However, building a model on multiple states’ data requires the data to be standardized, and without a common SIS to enforce uniformity, manipulating data into a common format is costly and time consuming.

Second, predictions must be surfaced to educators in a frequent and easy-to-use manner, which means the most successful systems will be closest to existing daily workflows. In some existing systems, staff members must log into a separate software program to access risk scores. In others, there are months between score updates. Timely prediction is important; the sooner a school is aware of a student at risk, the more time it has to intervene.

Infinite Campus provides a large student information system and has made significant investment in education data localization and standardization, reporting and warehousing, and user workflows for American K–12 education. Our role in the industry positions us to address the key remaining gaps in early warning systems using centralized data warehouses, standardized data, and placement of the early warning ap-

plication into the existing SIS.

Contributions

Available nationally in 32 states yet contextual to each child’s educational environment

Useful predictions: highly predictive, daily updates, four risk category scores, with consistent of predictive quality between protected student groups

Integrated into the student information system with no imports, exports or synchronization necessary

In the following section we describe our implementation of a dropout early warning system on more than 6 million student-years of educational records across 32 states. Our overall dropout risk score has excellent predictive quality with an AUC of 0.941 (see table 1 for additional quality metrics), and includes additional machine-learned scores that help counselors understand the source of a student’s risk to guide which interventions may be appropriate. Risk scores, delivered automatically and updated daily, are integrated into our existing SIS and available to counselors as an enhancement to their existing workflows.

2. IMPLEMENTATION

System design. Student data is stored in a number of relational SQL Server databases for school staff to create, read, update, and delete educational records. These databases exist in Infinite Campus’s fully owned and operated Tier 4 data centers that fulfill security requirements of the U.S. Department of the Interior. Student records exist in a variety of data structures and are recorded with varied time granularity for 45 states and the U.S. federal government, a portion of which we use for early warning. Because our model architecture requires a common data structure, we aggregate student records into a fixed format with one row per student-year, where ‘year’ corresponds to an academic year. Aggregated data is periodically transferred to a central repository in the same data center. Data for past students whose educational outcomes are known (e.g., graduation or dropout) is then used to build a machine-learned model relating summarized educational records to student enrollment outcomes. The model, along with summarized properties of each district, school, and geographic area present in the dataset, is deployed behind an API. Each day, records for currently enrolled students are aggregated, de-identified, and sent to the API, which returns risk scores for each student. Figure 1 illustrates this architecture. The returned risk scores and a score history is made available to counselors via the SIS user interface. By integrating and automating the process of generating and updating risk scores into the SIS, we relieve dropout prevention teams from the burden of collecting, storing, and analyzing the source data themselves.

What we predict. Each student-year of aggregated educational records is tagged with one of three labels: “needs early warning”, “does not need early warning”, or “ignore for early warning”. A student-year is labeled with “needs early warning” if the student’s records include known undesirable outcomes during the year in question or future years. For example, records for an 8th grader in 2014 would be labeled

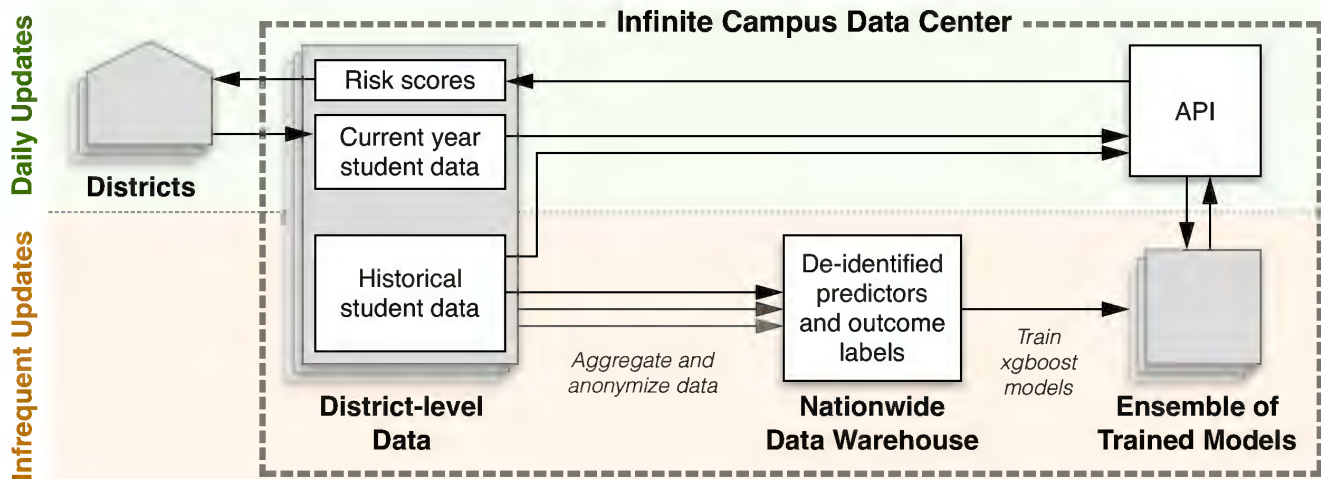

Figure 1: Schematic of architecture describing data flow for model training and prediction. Model training is performed infrequently, while risk scores are recalculated daily to incorporate new information. All data remains in the Infinite Campus data center and is not transferred to third-party servers. Identifying information is removed before transfer between systems.

“needs early warning” if they dropped out in 2016. We define undesirable outcomes based on enrollment end status codes identified by states as indicating school dropout, and expand the definition to include unsatisfactory academic progress (i.e., retention or demotion) and expulsion or other removal. A student-year is labeled with “does not need early warning” if the student had no undesirable enrollment outcomes during the year in question or future years, *and* we can confirm that the student persisted to graduation. If we do not know whether the student persisted to graduation—the student transferred outside of our system or is still enrolled—then the student’s data is censored and we lack ground truth labels for it. Each of these students’ years are labeled with “ignore for early warning” and excluded from training and evaluation. To translate state-specific enrollment status codes to outcome categories, codes were mapped by three independent raters, then differences were reconciled and validated by comparing resulting outcome rates across districts. Data from a school district are removed from training if that district has abnormally high “needs early warning” or “ignore for early warning” rates, as these conditions may indicate underlying inconsistencies in record-keeping that warrant further investigation. In addition, student-years are removed from training if the student’s cohort is not scheduled to have graduated yet, in order to remove label bias in earlier grades.

Our data collection and labeling process produces approximately 6.4 million rows of labeled data. We use 45% of rows for model training, 5% for model validation (to determine training stopping points), and 50% for final quality evaluation, split by student. Roughly 16% of training rows are labeled as “needs early warning”.

Predictors. Our training set is produced by collecting and summarizing educational information from the core SIS database. This summarized information relates to attendance, academic performance, behavior, household and enrollment

stability, and other items. We chose predictors that are consistent across states and districts and that are supported by the dropout prevention literature (e.g., [19]). Where data is localized, we employ experts who communicate directly with stakeholders in districts and states to ensure we understand the unique characteristics of local use and law. Attendance information includes the proportion of class time a student was actually present, as well as absences grouped by type of excuse. Academic performance information includes the proportion of course grades attributed to each letter grade, overall high school GPA, and the proportion of attempted credits successfully earned. Behavior information includes the number of behavior infractions and resolutions, as well as whether weapons, drugs, or harassment were involved. Household and enrollment stability information includes the presence of past undesirable enrollment outcomes and how often the student changes home addresses, schools, or districts in the middle of school years. Finally, we include contextual information such as age and grade level. In total, we have approximately 70 distinct predictors per year, and each student-year row includes the current and previous year’s data.

One core design goal for our system was to have a nationwide statistical model that is sensitive to local and contextual factors. We achieved context-specific performance with two types of feature engineering: including subpopulation aggregation features and calculating interactions among a student’s personal features as well as the subpopulation aggregates that apply to them. For example, a student’s attendance or academic data *relative to their peers* in a given group may carry information about risk. To allow for this possibility, we calculated two types of summary statistics for each school, district, and ZIP code in our dataset. For numeric predictors, we calculated the mean value per group. For categorical predictors, we calculated the proportion-per-group of each category. These group-level contextual features allow us to capture signals about students’ environ-

ments that are more informative than simple group-membership variables. The group-level information about each student-year's specific district, school, and ZIP code is joined on each student-year row for model building and prediction.

By including a wide range of features characterizing individual students and their educational environments, we allow the machine learning model to determine the significance of each feature and the relationship between features as they relate to risk. The wide range of potentially predictive features is simply not available to most non-SIS vendors. By using a relatively complex feature set and modeling architecture, we are able to capture complex contextual relationships between students and their environments.

Explanatory scores. While machine learning affords high predictive accuracy and the ability to capture complex relationships between predictive features, this comes at the cost of reduced model interpretability. In early conversations with customers, we were frequently asked *why* a student received a given risk score. To answer this question, we supplement our overall risk score with two types of explanatory 'category' scores that provide insight into which parts of a student's record are contributing to their overall risk.

The first set of explanatory scores is based on Balfanz's "ABC" categories [10]—attendance, behavior, and course performance—and an additional "stability" score including measures of household and enrollment stability. Each of the four scores is produced by a separate model trained only on predictors from its respective category. By partitioning the predictors according to category, we in turn are able to disentangle the impact each category has on the overall risk score. The predictive quality of category scores is necessarily lower than the overall risk score, because the category-specific models use a strict subset of the overall model's predictors. However, these scores indicate whether each category of a student's predictors, when taken by itself, is characteristic of a student with undesirable future enrollment outcomes.

In addition to scores built on subsets of predictors from each category, we also build scores for each category using a "counterfactual" approach. That is, if a student's records improved in a certain area (but the rest of the student's records stay the same), how would their risk change? To answer this question, we replace the values for the "actionable" predictors in a category with values corresponding to exemplary performance. The resulting data represents an attainable ideal for each student—if he or she attended every class, earned perfect scores on every assignment, or never behaved inappropriately. This data is used to produce a counterfactual risk score for each of the four categories, which when subtracted from the student's actual overall risk score indicates the potential "room for improvement" in each category; these are our final four explanatory scores.

While picking values corresponding to exemplary performance appears intuitive (e.g., 4.0 GPA, 100% attendance), using them to artificially modify student data has the potential to push the resulting data points outside the space of training examples, leading to unpredictable model behav-

ior. Preliminary analysis found this to be a problem for some "obvious" exemplary values, leading us to select values experimentally instead. For each feature, we used a statistical model to find the optimal bin (range of values) corresponding to the lowest predicted risk, which we subsequently validated by checking that the proportion of actual dropouts was lowest for this bin. We chose a reasonable value from each optimal bin to represent exemplary performance.

2.1 Modeling technique

The system described here must operate at scale within an industry setting and be robust to messy and missing data. To achieve this, we use the **xgboost** package [5] for modeling, which constructs a series of simple decision trees. Unlike logistic regression or neural networks, **xgboost** is robust to the presence of outliers and appropriately handles missing values. The decision-tree structure of model components provides an integrated way to capture contextual relationships between individual predictors and group-level aggregates. **xgboost** supports parallelization of model training, so training scales well on enterprise server hardware. We use the 'binary:logistic' training objective, so that **xgboost** models produce the probability of a student-year being labeled as "needs early warning". We use the area under the receiver operating characteristic curve (AUC) as the **xgboost** evaluation metric. AUC measures the quality of sorting produced by the model, with a high value for AUC indicating that the model is correctly assigning higher probabilities to student-years labeled as "needs early warning" than to those labeled as "does not need early warning".

Our modeling strategy ensures robustness to noise in two ways. First, we heavily regularize our **xgboost** models by using a small tree depth and relatively few training rounds, reducing over-fitting and making the model more robust to small changes in student data (both during training and during prediction). Regularization makes it possible to provide high-quality predictions for unseen data, such as a student in the evaluation dataset or a new customer whose data was not included in model training. Second, for each score type we train an ensemble of 11 to 25 **xgboost** models, and use the median prediction of all models. This technique further reduces variability between model deployments.

Predictions. Predictions are refreshed daily by aggregating educational records of currently enrolled students and sending those aggregates to our API, as illustrated in Figure 1, which provides GRAD scores and category scores back to the SIS. This technique allows us to provide score updates more frequently than competitors, and eliminates the requirement for school districts to transfer or analyze data on their own. The SIS then displays risk scores to staff members that have been given access to the early warning tool by district administrators.

As described above, we train the model using aggregations from past entire student-years. However, daily predictions are made for currently enrolled students, whose current year records contain only a partial year of data. We used several methods to mitigate the mismatch with our training dataset. First, in addition to aggregates summarizing a student's data from the current academic year, we also in-

clude aggregates from the student’s previous year as predictors. This allows the model to observe student data for an already-completed year and it affords analysis of year-over-year changes. Second, some data is in the form of event counts that accumulate throughout the year, such as the number of missed periods or the number of behavior resolutions. This data is converted into a rate, such as missed periods per instructional day. Rates are then directly comparable at all points in the academic year. Since rate-converted values are sensitive to small changes at the beginning of the school year, we instead use an ‘estimated rate’ calculated as a weighted combination of the previous and current year’s rates. After about four weeks of school, the previous and current year’s rates are equally weighted, with the current year’s rate weighted more heavily after each additional day.

We convert the probability output from `xgboost` into a user-facing “GRAD score” that ranges from 50 to 150, where 50 indicates high likelihood of undesirable enrollment outcomes in the future and 150 indicates high likelihood of persistence to graduation. We also considered that counselors may have a greater need to distinguish between students with low and moderate risk rather than between students with high and very high risk. That is, a 0.1 change in dropout probability from 0.05 to 0.15 is more important than a change in probability from 0.75 to 0.85. We therefore transform the raw probabilities to ‘spread apart’ students at the low end of the probability range (low risk), while compressing probabilities at the high end of the range (high risk).

2.2 Model evaluation

We evaluated our overall and subscore models on an evaluation set containing approximately 3.2M student-years (50% of the total dataset) that were not used for model building or validation during training. Results are listed in Table 1 and represent, as far as we are aware, the highest predictive quality in the industry. In Table 2, we also list evaluation results for our overall model by protected subpopulation [13]: sex, race/ethnicity, grade level, and free/reduced meal eligibility (a proxy for socioeconomic status).

Because counselors do not see predicted probabilities, but rather ordered GRAD scores, we chose the area under the receiver operating characteristic curve (AUC) metric that measures whether students’ predictions are ordered in terms of actual risk. The AUC effective range is 0.0 (perfectly inversely sorted) to 1.0 (perfectly sorted), with 0.5 indicating random predictions.

Futhermore, because counselors will give additional institutional resources to the few percent of students predicted most at-risk, we chose precision and recall metrics that measure whether how well that most at-risk prediction category actually contains at-risk students. We evaluated precision at 10% (P@10) and recall at 10% (R@10) following the literature [1]. A key limitation of precision@*k* and recall@*k* occurs when *k* is less than the population’s condition-positive (“needs early warning”) rate of the training set is 0.158. For subpopulation evaluation, precision and recall at baseline (PR@b) is based on that subpopulation’s own condition-

Model	AUC	P@10	R@10	PR@16
GRAD Score	0.941	0.865	0.549	0.719
Academics	0.914	0.825	0.524	0.682
Attendance	0.852	0.648	0.411	0.547
Behavior	0.808	0.582	0.368	0.493
Stability	0.860	0.654	0.415	0.548

Table 1: Risk score quality evaluation

Subpopulation	+ rate	AUC	P@10	R@10	PR@b
Female	0.130	0.935	0.770	0.597	0.683
Male	0.185	0.941	0.921	0.498	0.742
Hispanic	0.207	0.925	0.923	0.449	0.725
Asian	0.065	0.927	0.470*	0.712*	0.620
AIAN	0.275	0.927	0.972	0.354	0.771
NHPI	0.096	0.935	0.605*	0.676*	0.641
2+ races	0.185	0.935	0.909	0.487	0.717
White	0.134	0.937	0.790	0.592	0.692
Black	0.268	0.940	0.986	0.371	0.783
Not stated	0.136	0.951	0.871	0.639	0.762
6 th grade	0.218	0.896	0.918	0.421	0.695
7 th grade	0.212	0.910	0.924	0.434	0.709
8 th grade	0.207	0.921	0.921	0.444	0.716
9 th grade	0.232	0.937	0.978	0.423	0.779
10 th grade	0.169	0.937	0.888	0.529	0.727
11 th grade	0.112	0.940	0.730	0.654	0.692
12 th grade	0.079	0.953	0.573*	0.728*	0.649
NSLP: Free	0.252	0.919	0.961	0.385	0.737
NSLP: Reduced	0.130	0.920	0.745	0.579	0.652
NSLP: Paid	0.097	0.942	0.683*	0.700*	0.690
NSLP: N/A	0.125	0.942	0.788	0.634	0.711

Table 2: Overall model risk score quality for subpopulations. ‘+ rate’ refers to the baseline ‘condition-positive’ negative enrollment outcome rate for that subpopulation’s current or future enrollments. NSLP refers to the National School Lunch Program. AIAN refers to American Indian and Alaska Native. NHPI refers to Native Hawaiian and Pacific Islander. * means that the ‘+ rate’ value is less than 0.1 and therefore the effective maximum range of P@10 and R@10 is less than 1.0 for that subpopulation.

positive (“needs early warning”) rate. The effective range of PR@16 and PR@b is 0.0 (completely incorrect) to 1.0 (completely correct), with the random prediction rate equivalent to the baseline rate for that population.

3. LIMITATIONS AND EXTENSIONS

The use of year-level aggregates in model training erases temporal relationships between individual event records, making the system relatively blind to *patterns* of individual events within an academic year. To address this limitation, we are exploring alternate modeling strategies capable of ingesting event-based data streams that are both more granular and of non-uniform length. A second limitation is our model’s focus on grades 6–12. Interventions are most successful when they are applied early [21]. The ability to provide meaningful risk indicators for younger students could significantly improve outcomes by helping counselors target interventions toward the students who need them most, at the point they can ben-

efit from them most. To do this, we must overcome several data-consistency related obstacles, the most pressing being a lack of long-term datasets that are consistent in the type of information collected over time and the quality/reliability of the collection.

Finally, although target labels were created using inter-rater reliability methods, research on state policies, and student outcome data, the labels have not been verified by representatives from each school district who could personally attest to the accuracy of a given student's outcome. We intend to make the target calculation available to schools and to implement a system for users to provide feedback on our product's predictive accuracy to allow us to verify our labels and to continue to improve the quality of predictions.

4. CONCLUSION

We built a decision support system that provides high-quality, context-sensitive risk predictions and is integrated into an SIS that thousands of counselors already use in their workflows. In doing so, we offer daily risk assessments to millions of currently enrolled middle and high school students across the country. By automatically identifying students who may benefit from additional institutional resources in the service of timely graduation, we fulfill a key component of the dropout prevention process.

5. ACKNOWLEDGMENTS

We gratefully acknowledge all teams at Infinite Campus who have supported our work. We offer a special thanks to the Kentucky Department of Education and Kentucky educators for early partnership and feedback in this project.

ABSTRACT

Determining which students are at risk of poorer outcomes -- such as dropping out, failing classes, or decreasing standardized examination scores -- has become an important area of research and practice in both K-12 and higher education. The detectors produced from this type of predictive modeling research are increasingly used in early warning systems to identify which students are at risk and intervene to support better outcomes. In K-12, it has become common practice to re-build and validate these detectors, district-by-district, due to different data semantics and risk factors for students in different districts. As these detectors become more widely used, however, it becomes desirable to also apply detectors in school districts without sufficient historical data to build a district-specific model. Novel approaches that can address the complex data challenges a new district presents are critical for extending the benefits of early warning systems to all students. Using an ensemble-based algorithm, we evaluate a model averaging approach that can generate a useful model for previously-unseen districts. During the ensembling process, our approach builds models for districts that have a significant amount of historical records and integrates them through averaging. We then use these models to generate predictions for districts suffering from high data missingness. Using this approach, we are able to predict student-at-risk status effectively for unseen districts, across a range of grade ranges, and achieve prediction goodness comparable to previously published models predicting at-risk

1. INTRODUCTION

Graduating from high school is an educational achievement that is strongly linked to gainful well-paying employment, higher personal income, better personal health, reduced risk of incarceration, and lowered reliance on social welfare programs [23, 2]. Fortunately, graduation rates have been rising in the United States, trending towards reaching 90% nationwide by the year 2020 [18]. While this is a positive accomplishment, it leaves millions of students not completing high school,

representing a continuing crisis within the American educational system. This crisis is not evenly distributed; in the USA, there are much higher dropout rates for African American, Native American, and Hispanic/Latinx students [35, 19], up to 4 times the rate for White students, as well as for learners from low-income families and with disabilities [37].

There is a clear benefit in completing a high school education, so why do we still see alarmingly high levels of high school dropout? A great deal of research has been conducted trying to answer this one question, with the hope that once identification is achieved educators and administrators can apply a preventative or remedial intervention to curb student dropout [11]. However, many factors appear to lead to student dropout, including lack of social support from parents, poor motivation, low self-esteem, parental educational achievement and value, and economic factors, making it difficult to create a single intervention that works for all students [19, 30]. While demographic factors correlate with eventual dropout, these indicators are not considered actionable. A school district generally does not have the capacity to improve a student's economic condition, nor is it possible to alter a student's racial identity or gender. As such, the educational research community has focused on more actionable factors such as behavior, attendance, engagement, and social-emotional learning [21]. The most successful interventions have attempted to address issues related to specific indicators while also attempting to improve overall student academic engagement [14]. There are a range of potential interventions and many are costly, driving a need to identify the students that could benefit most from specific forms of support. Identifying these students can be a difficult task [10] which has led to an ongoing effort within the educational research community to determine which students are at risk of not graduating from high school [20] to apply proactive interventions that can help get students back on track [8].

This goal, along with the growing availability of student data, has led to Early Warning Systems, which leverage statistical methods applied to historical student data in order to predict outcomes for new students. Early work on predicting high school graduation tended to use statistical methods in order to infer the relationship between graduation and indicators such as grades and attendance. For example, the seminal Chicago Model developed an "on-task" indicator built from first-year high school student performance indicators and then used this newly defined feature within logistic regression to model student risk [1]. This method proved effective with 80+ percent accuracy in predicting student dropout, leading to high popularity and wide-scale implementation and use [6].

More recently, researchers have begun to leverage machine learning and data mining methods, sometimes termed predictive analytics, to find complex patterns associated with future

Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 732 - 737

student outcomes [28, 17]. In K-12 education, this approach was used by Lakkaraju et al. [29] to predict student dropout in two districts, finding that the Random Forest algorithm outperformed several other algorithms. Some of the efforts to use machine learning in predicting student success have been scaled beyond single districts to entire states [27]. However, it still remains a challenge to deploy predictive analytics for use in schools at scale. District data often contain substantial information about its schools and students: demographic data about the student and teacher populations, academic performance information, financial information, disciplinary actions, and attendance records [36]. However, in many school districts, data quality is limited, with key information only available by integrating across multiple data warehouses, incompatible student ID numbers, errors in data entry, and local idiosyncratic interpretations of often ambiguous data fields. Even when data is today excellent, key data from past years is often unavailable due to the absence of a formal data system or having a data system which is difficult to query. Semantics may also change -- for example, the definition of "not graduated" is not stable across years and contexts [35] -- but these changes may not always be clearly understood when reviewing past data.

One solution is to use models that involve simple variables that are feasible for almost any district's data and assume that model will be valid in new contexts, even where that context may be quite different from the context where the model was initially developed [32]. The Chicago model [1] is a common choice for this type of application.

In this paper, we propose and evaluate an alternate solution to providing a model for a new district. Our approach attempts to generate predictions for a specific "Target" school district based on models from other school districts where full datasets are available, using a simple average of the district models, where all existing models are given equal weight. We compare the quality of our averaging approach to the earlier solution of using a simple generic model, specifically, the Chicago model.

2. METHODS

In the following section, we will discuss our method for making at-risk student predictions for school districts which have insufficient data to create a district-based prediction model. In brief, we develop and validate predictive analytics models for each school district with sufficient data. These models predict each student's probability of graduating (or risk of not graduating). We then conduct a simple ensembling approach, averaging each model's predictions, to produce a single prediction for each student. We test the quality of this approach by conducting it for held-out districts where data is available.

We validate our new approach by comparing its performance to the widely-used "Chicago model" [1, 6] on the same test data and comparing the performance of our detector to the classic Chicago model, which can be used for entirely new districts with no re-training. The Chicago model utilizes freshman-year GPA, the number of semester course failures, and freshman-year absences to determine the student's risk of failing to graduate [1]. Since the Chicago model relies on data collected within the first year of high school, we were only able to compare the performance of our approach to the Chicago model for high school students.

2.1 Data

Data for this research originate from the BrightBytes data analytics and visualization platform, Clarity®. The Clarity® platform ingests disparate datasets, transforms them to a standardized format by mapping district-specific variables to a common schema, prepares the data for analysis, and then visualizes the data in a meaningful, easy-to-understand way. The Clarity® platform is used by 1 in 5 schools across 47 states to empower educational leaders to use data for decision making. The value derived by districts from the Clarity® platform comes from using data to drive change within an organization. The anonymized dataset used in this paper ($n=3,575,724$) represents a large spectrum of K-12 students in terms of free/reduced lunch eligibility, school urbanicity, and school demographic makeup, and is drawn from a range of school districts, educational organizations and agencies.

We have nearly complete data (with only small numbers of variables unavailable) from an educational agency with decision-making power over a large geographical region (Pillar 1) and three large individual school districts (Pillar 2, Pillar 3, Pillar 4). These datasets are referred to as "Pillars" because they serve as bases for our ensemble-based approach. The four Pillars differ in terms of their predominant student demographic groups, with Caucasians representing the largest group of students in Pillar 1 ($n=1,681,988$), Hispanic/Latinx students representing the largest group of students in Pillar 2 ($n=392,148$), and split demographics in Pillar 3 ($n=158,991$) and Pillar 4 ($n=140,132$).

We test our models on 30 "Target" districts that were not used to develop the models, due to having fewer years of data, more missing variables, or smaller samples overall. These Target districts span a diverse range of predominant demographics, with one Target district being over ninety percent Caucasian at one extreme, and other districts being almost completely Hispanic/Latinx or African American. District performance is equally as diverse: some Target districts achieve graduation rates over 90% while others have graduation rates as low as 36%. Table 1 below highlights the number of records available in the Pillar districts and Target districts. The Target districts are generally smaller than the Pillar districts, with some having as few as 271 total historical student records, with the percent of data missingness within the Target districts also quite high in some cases ($M=41.65\%$, $SD=7.498\%$).

Table 1: Average Number of Outcome Records in Target Districts

Grade Band	Graduates	SD	Dropouts	SD
1st – 5th	4,307	9,784	634	1,267
6th – 8th	7,673	16,837	996	2,012
9th – 12th	24,552	39,524	1,920	3,833
All Grades	12,177	95,962	1,183	7,377

2.2 Predictor Variables

The potential set of predictor variables was selected in partnership with the American Institutes for Research (AIR) team [22], this paper's authors, and other researchers and developers at BrightBytes. This collaboration resulted in a theory-based [9] framework of success indicators, along with definitions of those success indicators that are used to map and align district data. Due to the data ingestion and transformation

process, the same data features can be used across all districts. Below is a distillation of the broad range of potential variables into a small set of meaningful buckets:

General Coursework: student academic performance such as total credits earned or student grade point averages [25, 38, 5].

Student Assessments: interim or summative assessments related to math, science, reading and social studies performance [26,16].

Student Attendance: recorded as absences or tardies [33].

Student Behavior: disciplinary incidents the student has on file [4, 10].

2.3 Model Fitting

The first step toward building an at-risk prediction model for districts without sufficient data is to build models for districts with sufficient data. For each of these models, we took the data from a single district. We filtered down to only the students who were flagged as ‘dropped’ and ‘graduated’. Even if students took extra time to graduate, they were still counted as graduating. Only these students were used for building the model; all other outcomes (such as transferring to another school district) were removed from the filtered dataset. The resultant datasets were generally highly imbalanced, with substantially more students graduating than dropping out. To account for this imbalance, the training data was manually rebalanced by adding duplicate copies of students who dropped out to the data set. Specifically, duplicates were created such that every grade level (10th, 11th, 12th, etc.) of students in the training datasets had an equal number of students who dropped out as students who remained. The original data distribution was used when testing the models.

Decision trees, support vector machines, XGBoost, logistic regression and random forest were all tested to build the initial model. The best performance across data was obtained with random forest classifiers with $n=15$ estimators and a max depth of 10. Since the algorithm was tree based, we utilized arbitrary value substitution to replace missing values with a high integer [39]. The goodness of each district’s model was evaluated, within-district, using a train-test split method (note that models are also evaluated within entirely new districts; see below). In each case, the training set consisted of a randomly selected 70 percent of the data with label-based stratification used across grades. The test set held out to validate the model consisted of the remaining 30 percent of the data.

Models were evaluated using the Area Under the Curve for the Receiver Operator Characteristic graph. AUC ROC was selected as our primary evaluation statistic due to its interpretability and validity for highly-imbalanced test sets [24]. AUC ROC calculates the tradeoff between true positive and false negative for every possible threshold used for labeling data points as positive and negative; as such, it is well-suited for evaluating how well an algorithm ranks students relative to their risk.

2.4 Pillar Selection

Selection of the four Pillar districts was based on two factors, data quality and model performance. To evaluate data quality, we calculated the proportion of missing values within the total feature set, expressed as a percentage. Districts were not included as Pillar districts if they had high amounts of missing data, over 40% of values missing, as these districts would be less useful for modeling other districts where these features were present. Districts were also not included as Pillar districts

if they lacked historical data spanning all grades 1 through 12; districts without historical data for some grades would be less useful for developing models that could be applied to all grades.

Models developed for specific districts as potential pillar model candidates were fit and evaluated using held-out test sets from that district’s own data. Districts for which we were able to produce a model with AUC higher than 0.7 on the district’s test sample, averaged across all student class years, were designated as Pillar districts/models and used in our predictions for districts for which models could not be generated for all grade levels, or for which models were insufficient in quality. Of the 30 Target districts within our study, 25 do not have enough historical records spanning all 12 grades and 5 had sufficient data but were unable to produce an AUC over 0.7. All 30 districts suffered from at least some degree of feature missingness.

2.5 Applying Models to New Districts

Having developed models for Pillar districts, where data are abundant, data quality is high, and where it is possible to develop a high-quality model, we next applied each Pillar model to each Target district. These Target districts had at least one of the following attributes; 1) Under 20,000 students, 2) Over 40% missing values, 3) Missing historical records for some grades in K-12, 4) AUC ROC when applied to new students within-district.

Our first step to applying the Pillar models was simply to run each of them on the Target district’s data ($n = 1,202,465$) and obtain predictions for each student. This provides us with a set of predictions for each student and for each model. We then took the average of the probability estimates, across districts, to generate the final student prediction. When we applied Pillar models to Target districts, we evaluated these models using all historical records present in the data as none of their records were used within model training. As with models tested on the district for which they were built, we use AUC ROC as our metric of model goodness.

3. RESULTS

3.1 Within-District Performance

We first applied each Pillar district model to new students from the same district, to evaluate within-district performance. As shown in Table 2, the four Pillar districts achieved AUC ROC values ranging between 0.899-0.936 when predicting graduation/dropout, for 9th through 12th grades (the typical high school years in U.S. classrooms). Performance was moderately lower for 6th-8th graders, where longitudinal predictions of up to 6 years are being made, with AUC ROC ranging from 0.849-0.884. Performance was again moderately lower for 1st-5th graders, where longitudinal predictions of up to 11 years are being made, with AUC ROC ranging from 0.758-0.810.

Table 2. AUC of Pillar Model Performance on Pillar Model Test Data (new students) by Grade Band

District	1 – 5	6 - 8	9 - 12	Average
Pillar 1	0.778	0.849	0.899	0.865
Pillar 2	0.758	0.884	0.908	0.858
Pillar 3	0.810	0.884	0.936	0.888

Pillar 4	0.794	0.850	0.903	0.886
----------	-------	-------	-------	-------

Our attempts to build a model for each Target district proved less successful, with 9th – 12th grade model AUC averaging 0.729, 0.1825 lower than for the Pillar Districts, 6th-8th model AUC averaging 0.669, 0.198 AUC lower than the Pillar Districts, and 1st -5th grade obtaining an average AUC of 0.635, 0.15 points lower than the Pillar Districts' within-district performance for these grade levels.

It should be noted that there were three exceptions to this poor AUC trend. Three Target districts produced relatively more successful models, averaging AUC = 0.81 for 9th-12th grade students, AUC = 0.709 for 6th-8th grade students, and AUC = 0.666 for 1st-5th grade students. Despite the initial successful results of these three Target districts, they still lacked the data to produce models for all years, with all three missing records for 1st and 2nd grades. When additional historical records become available in the future, these models will almost certainly make it into the pool of Pillar models in future model iterations.

3.2 Feature Importance

We can understand which features are particularly important to each Pillar model by calculating feature importance. Feature importance was calculated using the mean decrease impurity method, sometimes referred to as the *gini importance* [12]. This metric allows us to calculate how much each feature contributes to the model's eventual predictions of a student's outcomes (in this case, risk of dropout). A range of different types of features were found to be important in the four models. The Pillar 1 model relied heavily on features related to student age, attendance and academic achievement. The Pillar 2 model was similar to the Pillar 1 model in that it relied strongly on academic and attendance related features. However, student summative reading scores were also important to the Pillar 2 model. The Pillar 3 model was less similar to the first two Pillars. For Pillar 3, student assessment data and student behavioral data (i.e., disruption, defiance, etc.) were the primary contributors to the model's predicted outcomes, a difference in feature importance that is likely due to a multitude of reasons. Pillar 4 was most similar to Pillar 1 as it also relied heavily on student academic indicators. One reason could be that there were differences in the data availability of features for each district. For example, no assessment data was available for Pillar 1, whereas Pillar 3 had assessment data available for almost all of their historical student records. Another cause could be the difference in the populations of students in each Pillar district. For example, attendance may play a larger role in graduation in urban districts (e.g. Pillar 2), whereas behavioral incidents could play a larger role in the path to dropping out for students in more rural districts (e.g. Pillar 3).

3.3 Performance on New Districts

We applied the Pillar models to each student's data from the 30 Target districts, and averaged the probability across models for each student. These districts had considerable variation in size, graduation rate, and degree of missingness of data (and which features were missing), with values for these variables that were substantially higher or lower than the values for the Pillar districts. In other words, applying models from the Pillar districts to these thirty Target districts represents substantial extrapolation.

Table 3 shows average performance of each individual Pillar model detectors on the Target district data, as well as using averaged probabilities. Despite the high degree of extrapolation required, performance was generally good, with an average AUC (across districts) of 0.783 ($SD = 0.100$), with three districts achieving AUC above 0.9. AUC results within grade band produced similar outcomes, with 9th-12th obtaining an average AUC of 0.813 ($SD = 0.078$), 6th-8th model AUC averaging 0.736 ($SD = 0.13$), and 1st -5th grade model AUC averaging 0.646 ($SD = 0.141$). However, two districts (Target 12 and Target 28) had poor overall AUC values of 0.539 and 0.469. It is worth noting that these two districts had the highest rate of missing data for features that ranked most important in the Pillar models, with over 80% of students in these Target districts missing data related to coursework, over 90% of the records not containing any assessment scores, and the data for 40% of the students not containing attendance information. Overall, the districts with the highest amounts of missing data in core features were also the districts with the lowest AUC ROC values. None of the individual Pillar models did as well as their average when applied to the Target districts; individual Pillar models achieved an AUC between 0.718 - 0.756 on the Target districts, significantly underperforming compared to averaging the produced model probabilities.

Table 3: Average Performance of Pillar Model and Mean Detectors on Target District Data.

Detector	1 – 5	6 - 8	9 - 12	All Grades
Mean Model	0.646	0.74	0.813	0.783
Pillar 1 Model	0.631	0.673	0.749	0.719
Pillar 2 Model	0.568	0.678	0.764	0.718
Pillar 3 Model	0.631	0.720	0.789	0.750
Pillar 4 Model	0.591	0.685	0.788	0.756

3.4 The Chicago Model On-Task Indicator

Comparing our Mean Model detector to the Chicago model detector was limited by data availability: the Chicago model relies on freshman year high school student data, specifically the number of course credits and courses failed during freshman year (9th grade). Due to the detector's reliance on these two data points, our validation sample was limited to only those districts that contained valid information for these two features. However, many of our Target districts lacked data for the features in the Chicago model, for some students. If at least one feature was available for the Chicago model, the model was used; a student was assigned a .5 probability of graduating if the Chicago model was missing all features and therefore incapable of producing a prediction. The Pillar models performed also poorly for these students with very high data missingness.

Table 4: Average AUC Performance of Mean Model vs. Chicago On-Task Indicator: 9th-12th grades

Detector	Avg AUC	Standard Deviation
Mean Model	0.821	0.084
Chicago Model	0.624	0.121

The Mean Model outperformed the Chicago model in every Target district, except for one district. In that district, the Chicago model ($AUC=0.77$) performed .068 better than the Mean Model ($AUC=0.702$). Overall, the mean Pillar model

detector achieved an average AUC of 0.197 higher than the Chicago model when measuring performance of predictions on high school student Target district data.

One might argue that this comparison biases against the Chicago model, by including cases where the specific data needed was unavailable. Although our approach is designed to work in cases of high missingness, we can also compare our Mean Model to the Chicago Model only for cases which have the data the Chicago model needs. This resulted in a significant reduction of the data used to calculate AUC metrics, with only 351,902 out of the original 1,202,465 student records able to populate the On-Track Indicator, 29.3% of our initial sample.

Table 5: AUC Performance of Mean Model vs. Chicago On-Track Indicator on Complete Records: 9th-12th grades

Detector	Avg AUC	Standard Deviation
Mean Model	0.874	0.061
Chicago Model	0.734	0.082

Both the Mean Model and the Chicago Model saw an increase in their average model performance across the new sample, with the Mean Model increasing by 0.053 from 0.821 to 0.874 and the Chicago model increasing by 0.11, from 0.624 to a more respectable AUC of 0.734. However, the Mean Model still achieves an AUC 0.14 higher despite these conditions designed to be more favorable to the Chicago Model.

4. CONCLUSIONS

In this paper we propose an approach to predict student risk of not graduating from high school for districts where the quality, quantity, or availability of data is insufficient to produce a satisfactory model of student risk, using an ensemble of models from other districts where data is available. This method achieves good predictive power for students in districts that were not used to develop the model, without any fitting or modification to the models or their application. Furthermore, it achieves substantially better results than a popular alternate approach to predicting at-risk status in new districts, the Chicago model.

It is worth noting that our approach and study have several limitations that should be investigated in future work. Though our sample of Target districts was large, we have not yet applied this method across the full diversity of students in the U.S. In particular, districts with substantial Native American populations or those located in extremely rural regions, such as northern or western Alaska, are not represented in our study. Similarly, we have not studied whether our models are equally good for all subgroups within the school districts—a limitation that is common in the field.

There are several ways in which we could probably improve model performance. Research has shown that contextual factors can contribute to identifying students at risk of dropping out and that factors associated with dropout can differ between populations [7, 15]. Altering the detector to weight the Pillar model probabilities by leveraging characteristic information such as student and school demographics, urbanicity (urban, rural, suburban), and the proportion of military-connected or otherwise highly-mobile students could help account for similarities between students and districts better. Additionally, future iterations of our method could take an empirical approach

to selecting the Pillar model weights using measure of similarity based on model performance [31], rather than limiting the approach to the current simple averaging method where features are weighted equally.

Ultimately, the performance of the Mean Model presents new opportunities in identifying students at risk of dropping out for districts with minimal or no data. Given the potential benefit of interventions for at-risk students, this new approach has the capacity to improve the future of student outcomes within a large number of schools where it is not yet possible to develop predictive models. Students educated by districts where data are insufficient can now be presented with greater opportunities through the use of proactive interventions driven by predictive modeling rather than being limited to receiving reactive interventions that are often applied too late, if ever.

ABSTRACT

The Additive Factor Model (AFM) is a cognitive diagnostic model that can be used to predict student performance on items in a context that allows for student learning. Within AFM, *skills* have a learning rate, and student acquisition of a skill depends only on the number of opportunities a student has had to exercise that skill and the learning rate of that skill. Here we demonstrate an approach to measure the *teaching value* of individual *items* with respect to one another. The teaching values estimated through this approach may be useful for structuring intelligent tutoring systems and for content improvement.

Keywords

cognitive diagnostic models, item response theory, knowledge tracing, data mining, content pedagogy, content improvement, priming.

1. INTRODUCTION

Item Response Theory (IRT) models describe the performance of students with respect to a set of scored items (questions). As described by Sijsma and Junker [5], most IRT models have three assumptions:

1. Local independence: Student performance on a given item does not depend on student performance on previous items.
2. Monotonicity: The probability of student success on an item increases when student ability improves.
3. Unidimensionality: Each student has the same ability for every item, and each item has the same difficulty for every student.

The simplest IRT equation, the 1-parameter logistic model or 1PL, can be expressed as

$$P(Y_{ij} = 1 | \alpha_i, \beta_j) = \frac{e^{\alpha_i - \beta_j}}{1 + e^{\alpha_i - \beta_j}} = f(\alpha_i - \beta_j)$$

where $f(x) = 1/(1 + e^{-x})$ (resulting in a probability in $(0, 1)$), Y_{ij} is the response of student i on item j (with 1 for correct, 0 for

incorrect), α_i is the ability of student i , and β_j is the difficulty of item j .

Multidimensional IRT (MIRT) models relax the third assumption, decomposing student abilities and/or item difficulties into an array of abilities or difficulties. The Additive Factor Model (AFM) proposed by Cen et al [2] can be viewed as a MIRT model that also relaxes the local independence assumption, taking into account multiple exposures to a skill through a learning rate for that skill. The probability of student success is expressed as:

$$P(Y_{ij} = 1 | \alpha_i, \beta, \gamma) = f\left(\alpha_i + \sum_{k=1}^K \beta_k q_{jk} + \sum_{k=1}^K \gamma_k q_{jk} t_{ik}\right)$$

where $f(x)$ is again the logistic function $1/(1 + e^{-x})$, β_k is the difficulty (or easiness, with the sign reversed) of *skill* (rather than item) k , q_{jk} is a binary indicator that item j uses skill k , γ_k is the learning rate of skill k , t_{ik} is the number of exposures student i has had to skill k , and K is the total number of skills assessed. If each item addresses only one skill, the first sum reduces to β_j . If the learning rate is 0, the second sum reduces to 0, resulting in the 1PL equation.

In AFM, the likelihood of a student acquiring a skill is impacted only by the constant learning rate of that skill and the number of exposures that student has had to that skill. Here we seek to estimate a new quantity, the *teaching value* of an item with feedback. Exposure of a student to an item with a positive teaching value increases the probability that that student will answer a subsequent question correctly.

2. METHODOLOGY

Macmillan Learning's homework system examined in this study serves items (questions with automatic grading and feedback) to students, with the items grouped into assignments. The items investigated in this study were used across 570 institutions of higher learning in 4,704 courses. The order of the items in the assignments could be partially or fully randomized, and could be edited manually by individual instructors. As a result, a given item could be the first item in an assignment for some students, the second for others, etc., even within the same course.

We began with a dataset containing 240,990 unique students interacting with 7,257 unique general chemistry items, resulting in 29,005,495 student-item interactions. To simplify this proof of concept, we assume that all questions measured a single skill ("general chemistry knowledge"). To measure the impact of questions on one another, we define an *experience* as a set of one, two, or three items presented to a student in a particular order, starting with the first item in the assignment. For each experience,

Jon Harmon and Rasil Warnakulasooriya "Measuring Item Teaching Value in an Online Learning Environment" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 738 - 741

we scored the experience as *correct* (1) iff the student was scored as correct on their first attempt on the *last* item in that experience, and *incorrect* (0) if they were scored as incorrect on their first attempt on the *last* item in that experience, regardless of how they performed on any previous items. Using the dplyr package [7] for the R programming language [3], we filtered the full dataset to 32,199 unique students, 1,264 unique one-item experiences, 1,956 unique two-item experiences, and 1,567 unique three-item experiences, resulting in 3,240,791 student-experience interactions, using the following conditions:

1. The experience contained one, two, or three items.
2. Every item within each experience was attempted by at least 100 students as the *first* item in their assignment.
3. Every experience was attempted by at least 100 students.
4. Each student attempted at least 50 experiences.

By treating each experience as a single item, we were able to model the student abilities and difficulties of questions using a relatively simple IRT model. In this study we used the two-parameter logistic model (2PL) described by Birnbaum [1]. In the 2PL, items are allowed to have varying difficulties (β) and discrimination values (the ability of an item to differentiate between a low-skill student and a high-skill student, herein denoted a). The probability (P) of a student with ability θ answering a question correctly is given by:

$$\ln\left(\frac{P}{1-P}\right) = a(\theta - \beta)$$

For the 2PL, it is assumed that the chance of a student *guessing* the correct answer is 0. The item and student parameters can be estimated using marginal maximum likelihood estimation (MML). Here we used the TAM package [4] to perform the estimations.

We fit the filtered student-experience interactions to a single two-parameter logistic model. To illustrate the approach in detail, our focus in this paper will be on the two-item experiences.

We define the *raw difficulty* (β_A) of a given item A as the modeled difficulty of item A when it is the *first* item attempted by students (i.e., when it is presented in a one-item experience). We define the *apparent difficulty* ($\beta_{A|B}$) of a given item A with respect to another item B as the modeled difficulty of item A when it appears *second* in a two-item experience, after item B. We calculated the *difficulty change* of a given item A after item B as the difference between the apparent difficulty and the raw difficulty for that item in that experience.

$$\Delta\beta_{A|B} = \beta_{A|B} - \beta_A$$

A *negative* difficulty change indicates that item A appears to be *easier* when it follows item B, and a *positive* difficulty change indicates that item A appears to be *harder* when it follows item B. For this study, we did not constrain the time between a student answering item A and that student answering item B.

3. RESULTS

Two "goodness of fit" statistics were used to evaluate the fit of each experience to the model: outfit and infit. Both measures are expected to have a value close to 1.0 for each experience if the model fits the data without overfitting or underfitting. 92% of experiences had outfit of 1.0 ± 0.05 (standard deviation), and 99% of experiences had infit of 1.0 ± 0.05 (standard deviation). We analyzed two-item experiences which met these criteria: 1) the

experience had infit and outfit between 0.95 and 1.05, and 2) the second item of the experience had infit and outfit between 0.95 and 1.05 when it was in a one-item experience. Seventy six percent (1,490 of 1,956) of two-item experiences met these criteria.

The median difficulty change for these experiences was found to be -0.085 , with the second quartile beginning at -0.42 , and the third quartile ending at 0.27 . We focused our analysis on experiences with difficulty changes more than 1.5 interquartile ranges above the third quartile or below the second quartile, and defined these difficulty changes as significant. Other difficulty changes may also be statistically significant, leading to net learning effects. However, the educational significance of such effects remains to be explored in future studies. We observed that 22 item pairs (1.5%) had a difficulty change more than 1.5 times the interquartile range below the first quartile, indicating a significant *decrease* in apparent difficulty (the items appeared to become significantly *easier*), as we expected would occur. Somewhat surprisingly, 17 item pairs (1.1%) had a difficulty change more than 1.5 times the interquartile range above the third quartile, indicating a significant *increase* in apparent difficulty (the items appeared to become significantly *harder*) (see Figure 1¹). The remaining 1451 item pairs (97.4%) did not have a significant change in apparent difficulty as defined here. We examined specific cases of each type of change in apparent difficulty to attempt to identify the sources of the difficulty changes.

Figure 1. Most difficulty changes (the second and third quartile, shown in the box here) were near zero. However, some items showed a decrease in apparent difficulty (points at the bottom of the plot, lying more than 1.5 times the interquartile range below the second quartile), and some items showed an increase in apparent difficulty (points at the top of the plot, lying more than 1.5 times the interquartile range above the third quartile).

3.1 Decrease in Apparent Difficulty

Here we examine a specific case of difficulty changes in which the second item appears to be *easier* for students who have been primed by a specific preceding item. The item we designate "item A" in this study asks the student to

Give the conjugate acid for each compound below.

with three randomly selected bases such as HSO_4^- , CO_3^{2-} , and NH_3 . The student must enter the conjugate acid for each base (in this example, H_2SO_4 , HCO_3^- , and NH_4^+). The item we designate "item B" is effectively the opposite question, in which the student is given three acids, and asked to enter the conjugate base. Even when the

¹ All figures were generated using the ggplot2 package for R [6].

randomly selected acids and bases do not line up from item B to item A for a given student, students perform significantly better when primed by item B before answering item A, or *vice versa*.

Figure 2. When a specific item A followed a specific item B (green), students performed better than when item A was the first question (gray); the curve shifted up and to the left, indicating that students with lower skill became more likely to answer the question correctly. The curves indicate the modeled difficulty and discrimination for each experience, while the boxes indicate the 95% confidence interval of actual student performance (% of students in a given modeled skill group who scored correct on the experience on their first try). See Figure 3 for the same items in the opposite order.

Figure 3. When item B followed item A (green), students performed better than when item B was the first question (gray). See Figure 2 for the same items in the opposite order.

In contrast, the item we designate "item C" is within the same general topic, asking the student to

Label each reactant and product in this reaction as a Brønsted acid or base.

and showing the reaction between HCN and NH_2^- to produce CN^- and NH_3 . Item C does *not* have a significant impact on student performance on item A (data was not available for student performance on item B after item C).

Figure 4. When item A from Figures 2 and 3 followed a third specific item C (yellow), there was no significant change from when item A was the first question (gray).

The raw difficulty for item A was found to be 0.45 ± 0.05 (95% confidence interval reported on all fit difficulties). When item A followed item B, the apparent difficulty was -0.9 ± 0.1 , a difficulty change of -1.4 ± 0.1 (see Figure 2). Similarly, the raw difficulty for

item B was 0.5 ± 0.1 and the apparent difficulty after item A was -0.7 ± 0.1 , resulting in a difficulty change of -1.2 ± 0.1 (see Figure 3). In contrast, when item A followed item C, the apparent difficulty was not significantly different from the raw difficulty (0.7 ± 0.4 vs 0.45 ± 0.05) (see Figure 4).

3.2 Increase in Apparent Difficulty

Here we examine a specific case of difficulty changes in which the second item appears to be *harder* for students who have been primed by a specific preceding item. The item we designate "item D" asks,

Parts per million (ppm) is a common way to express small concentrations of a solute in water. A sample of tap water that is 25 ppm Cl^- contains 25 grams of Cl^- for every 1,000,000 grams of water. Which units are numerically equal to ppm for dilute aqueous solutions?

Students are given 5 choices in a random order: "g/L", "cg/L", "mg/L", "μg/L", and "ng/L". The correct answer is "mg/L".

A possible explanation for this effect can be found by examining the terminology used in each item, and the particular choices that students selected. Item E asks students to

Match each term with its definition or description.

with eight terms, including "parts per million." In the item we designate "item E," parts per million is defined as "micrograms of analyte per gram (or mL) of sample." In other words, Item D defines ppm in terms of L ("mg/L"), and item E defines ppm in terms of mL ("μg/mL"). Students who answer item E before item D are more likely to answer item D incorrectly, and they are more likely to do so by choosing the incorrect answer "μg/L" (see Figure 5). These results imply that students were led astray by the similarity of numerators of the units.

Figure 5. When item D followed item E (red), students chose "μg/L" more often than when item D was the first question (gray).

The raw difficulty of item D was 0.2 ± 0.3 . When item D followed item E, the apparent difficulty was 1.9 ± 0.4 , a difficulty change of 1.7 ± 0.4 (see Figure 6).

Figure 6. When item D followed item E (red), students answered incorrectly more often than when item D was the first question (gray); the curve shifted down and to the right, indicating that students required higher skill to have an equal probability of answering correctly.

4. CONCLUSION

We have shown that, adopting the methodology described above, we can measure the impact of individual questions with feedback on the difficulty of subsequent questions. This approach has implications for developing and revising pedagogically sound content. This approach could also influence sequencing of content to reinforce learning. Further research is required to attempt to generalize this difficulty change into a per-item “teaching value” parameter, but there appears to be evidence for this approach.

Items can have both positive and negative priming effects on the apparent difficulties of other items. Further research is required to determine the extent to which this effect increases or decreases with greater time in-between items, and whether intervening items have an impact on this effect.

5. ACKNOWLEDGEMENTS

JH would like to thank Jonathan Bratt for serving as a sounding board as this process was developed and for continued feedback throughout the process. JH and RW thank Adam Black for the opportunity to conduct this study.

ABSTRACT

Clustering of educational data allows similar students to be grouped, in either crisp or fuzzy sets, based on their similarities. Standard approaches are well suited to identifying common student behaviors; however, by design, they put much less emphasis on less common behaviors or outliers. The approach presented in this paper employs fuzzing clustering in the identification of these outlier behaviors. The algorithm is an iterative one, where clustering is applied, outliers identified, the data restricted to the outliers, and the process repeated. This approach produces a clustering that is crisp between each iteration and fuzzy within. It arose as a consequence of trying to cluster student progress trajectories in an adaptive learning platform. Included are results from applying the repeated fuzzy clustering algorithm to data from multiple courses and semesters at the University of Central Florida, (N=5,044).

1. INTRODUCTION

Personalization holds the promise of making learning more engaging and effective for students. Each student can receive personalized feedback and guidance based on their interaction with the learning material and their current needs and goals. Key to being able to provide this is an understanding of the full range of learning behaviors that students can exhibit, and the driving forces behind them. Truly personalized learning needs to understand not just the most common behaviors, but also those that are more atypical or outliers.

A variety of techniques have been employed to uncover student behaviors in different learning contexts [22]. Clustering is a common approach with a considerable range in both the applications and the algorithm employed [25]. Applications have included adapting question delivery, promoting group-based collaboration, and the characterization of atypical student behavior.

This work presents a clustering approach to automatically detect and quantify the range of behaviors, including the

Figure 1: Student progress trajectories. The gray lines show the trajectories for all 5,044 students at UCF. The colored lines highlight several individual trajectories.

outliers, that are evident in student progress data, in order to provide feedback to instructors on their student's behaviors. This goal throws up two restrictions on our approach. First, the clustering of behaviors must be fully automated. Not all instructors will have the required knowledge to make decisions such as picking the parameters of the clustering algorithm. Therefore these decisions need to be handled by the algorithm. Second, the output from the clustering must be readily interpretable by an instructor, including both understanding what makes a cluster a cluster, but also easily understand the differences between clusters. These two restrictions provide a means of measuring the ultimate effectiveness of the algorithm and the quality of the clusters that it produces.

In [11], the authors examined student progress data against time for an online course delivered at the University of Central Florida (UCF) through the Realizeit adaptive learning platform. The course was self-paced with students free to set their rate of progress. While most set a steady, consistent pace over the 15-week term, some students set a very different pace. These outliers roughly fall into two categories: students who race ahead of the rest, and those who fall behind, leaving all their learning to the last minute.

Figure 1 provides an understanding of the challenges when clustering these progress trajectories. The x-axis represents time in days, and the y-axis is progress measured as the percentage of concepts mastered. The progress trajectories for 5,044 students across 51 online course instances in 9 terms

Colm Howlin and Charles Dziuban "Detecting Outlier Behaviors in Student Progress Trajectories Using a Repeated Fuzzy Clustering Approach" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 742 - 747

at UCF are shown in gray. Each line represents a single student. Patterns are difficult to distinguish, but the consistent trajectory of most students through their course is evident along the diagonal. Five progress trajectories (colored lines) have been singled out to highlight the range of possible behaviors. The challenge in clustering this data comes from the fact that clustering algorithms, by design, attempt to group the data into as few clusters as possible and therefore put much less emphasis on outliers. They seek the most common patterns. Our goal is to find both common and outlier behaviors.

Our approach draws inspiration from He et al. [16, 17] who used clustering to search for hidden communities in social networks. In their work, they first used clustering to discover the most apparent communities. They then decreased the weights on the edges in the social network that represented these communities. Repeating the clustering uncovers previously hidden communities. Our approach, repeated fuzzy clustering (RFC) uses a similar technique where clustering is applied, outliers identified, the data restricted to the outliers, and the process repeated. The purpose of this paper is to describe and demonstrate the RFC algorithm.

Algorithmic clustering methods are essentially “blind” in that there is no linguistic functioning in their process. The categories identified are impervious to shared characteristics that ground themselves in cultural beliefs. However, the linguistic and algorithmic categorization processes do have common intersections. Linguistically, Rosch, [23, 24], described this as prototype theory where through any number of cultural and societal processes what is the best representational icon of a category is formed by our preconceived notions. Adaptive learning provides diverse paths to success, many of which may not align with our preconceived notions of what constitutes successful or unsuccessful behavior. Clearly, clustering algorithms have assumptions built into them a priori but once built are not influenced by preconceptions. The questions we ultimately wish to address involves whether or not the clustering of student trajectories can provide a foundation for category characteristics through the multiple lenses of methods, education, linguistics, and prototype theory and should they make educational sense how can we use them to improve learning? [20].

2. APPROACH

Here we provide an outline of the RFC algorithm. In the following subsections, we provide the specifics on our implementation of each function, although it is possible to alter these to suit other needs or implementations. The algorithm proceeds by first grouping students using fuzzy clustering for a range of values of k (the number of clusters) - lines 5 \rightarrow 7. Validity indices are calculated for each solution, and the most appropriate number of clusters is chosen - line 8. The algorithm then proceeds by identifying outliers and removing them from the data. The algorithm then reapplies the clustering creating a more compact solution. This part of the process repeats until the algorithm identifies no new outliers - line 10. The data is then limited to the previously identified outliers on this loop - lines 11 \rightarrow 12. The whole process then repeats with the data filtered to the outliers.

There are three parameters to the algorithm: k_{max} is the

Algorithm Repeated Fuzzy Clustering

```

1:  $D$  is the student data
2:  $Outliers = All\ students$ 
3:  $i = 0$ 
4: while  $|Outliers| > tol \ \& \ i < M$  do
5:   for  $k$  in  $1 : k_{max}$  do
6:      $F_k = FuzzyCluster(k, D)$ 
7:      $V_k = ValidityIndices(F_k)$ 
8:   end for
9:   Select  $k$  using  $V$ 
10:   $i = i + 1$ 
11:   $FC_i = RefineClustering(F_k)$ 
12:   $Outliers = IdentifyOutliers(FC_i, D)$ 
13: end while

```

maximum number of clusters to consider at each repetition; tol is limit on the number of outliers that must be present for the algorithm to repeat; M is the maximum number of repetitions. There are four functions within the algorithm where choice is possible. These enable the tailoring of the algorithm to specific needs or implementations. The choices here can lead to the introduction of additional parameters.

2.1 Fuzzy Clustering

Fuzzy clustering is used to determine the grouping of students within a loop. The choice of fuzzy, as opposed to crisp, is because it provides a membership value for each student in each cluster. This is relied upon to determine outliers, S2.4. In this implementation fuzzy k-means [10] is used, although it would be possible to use any other fuzzy clustering algorithm in its place [14]. An effect of using fuzzy clustering in our approach is that the algorithm produces crisp divisions between loops and fuzzy divisions within.

2.2 Validity Indices

Validity indices provide a quantitative measure of cluster validation. Their calculation is a fundamental part of the clustering process and provides guidance when deciding on k , the number of clusters. There is a huge range of cluster validity indices [2] with a large subset focused on fuzzy clustering [26]. In this implementation, we use the six available in the FClust R package [12]. These include the Silhouette index [19], Fuzzy silhouette index [5], Partition coefficient [3], Modified partition coefficient [8], Partition entropy [4], and Xie and Beni index [27]. For each clustering solution, we record the value of k recommended by each validity index. The final value of k is the mode of these recommendations. In the case of two possible values for k , we chose the smallest.

2.3 Refining Clusters

Refining the clustering solution is an optional step that enhances the compactness of the final clusters on each loop. Given a solution, outliers once identified are removed from the data. The clustering procedure is then rerun with the same value of k to derive a tighter clustering solution that better represents that data and students that remain. This process repeats as required until a stable solution emerges and no outliers are present.

Figure 2: Radviz of membership for a solution with $k = 6$. Outliers are shown in blue. (a) Outliers as identified by (1). (b) Outliers as identified by (2).

2.4 Identifying Outliers

Identifying outliers is the most crucial step in the RFC algorithm. This process places the split in the data for each loop of the algorithm. Many strategies are possible with the choice depending on the application and chosen clustering procedure. [21], [15] and [13] all explore identifying outliers as part of the k-means clustering process. This is done for several reasons including creating more compact clusters. These process generally rely on distance measures to identify the outliers in the data.

The method presented here identifies outliers using the membership values from fuzzy clustering with two versions considered below. The rationale behind both of these approaches is that they seek a solution which places observations mostly within one or two clusters. Any observation split among three or more clusters is an outlier. For an instructor having a student predominately within only one or two clusters should help simplify the task of interpreting their behavior.

The first and simplest version of identifying outliers uses the maximum membership value m_i and the sum of the two highest membership values s_i for an individual observation i . The condition classifies an observation as an outlier if the values of m_i or s_i fall below some limit. Equation (1) places a limit of $\frac{1}{2}$ on the value of m_i and a limit on s_i that increases slowly from $\frac{1}{2}$ with increasing number of clusters k .

$$Outliers = \left\{ i \mid m_i < \frac{1}{2} \vee s_i < \frac{1}{2} + \frac{1}{k} \right\} \quad (1)$$

This condition will not work for $k = 2$ as s_i will always equal 1, and the condition on m_i will never be satisfied. In this case, one possible solution would be to place a stricter limit on m_i and drop condition on s_i .

The second approach makes use of the Radviz method of visualizing fuzzy cluster membership [18]. Radviz represents each cluster by a dimensional anchor and distributes each dimensional anchor evenly on a unit circle. Each observation corresponds to a point. The visualization connects each point to each anchor by a spring whose stiffness corresponds

to that observation's cluster membership for the associated anchor. The position is where the spring's tension is at its minimum. Imagine each anchor pulls on a data point with a strength equal to the cluster membership. The higher the membership value, the stronger the pull and the closer the data point to that anchor. The ordering of the anchors is essential, and work has been completed to determine the optimum position [9].

The advantage of this method is that it makes observations which are evenly split among multiple clusters evident as these will be close to the center of the visualization since they get equally pulled in all directions. Observations that are a member of a small number of clusters will generally be further from the center. An example of a Radviz, created using [1], from one stage of implementing the RFC algorithm with six clusters, can be seen in Figure 2. In part (a), outliers, as defined by (1) with $k = 6$, are colored in blue and are visible in the center of the graph.

An alternative to (1) is to use the position of each observation on the Radviz graph. Here outliers are defined as being those at the center of the graph within some circle of radius r and where x_i and y_i are the Cartesian coordinates of the position of the observation i in the visualization. The parameter r has a similar role to m in the fuzzy k-means algorithm in that it controls the fuzziness of the clusters. The larger r , the crisper the clustering.

$$Outliers = \{ i \mid x_i^2 + y_i^2 < r^2 \} \quad (2)$$

This method has the advantage of also working without modification for the case where $k = 2$, as points become spaced along a straight line. In this case, the condition 2 reduces to $m < r + \frac{1}{2}$. Figure 2(b) displays the outliers as identified by (2) using $r = 0.4$. We can see a significant overlap of points using both conditions.

3. EXPERIMENTAL RESULTS

3.1 Dataset

The data used to test the algorithm is from UCF's use of the Realizeit platform. The data encompasses $N = 5044$ students across 51 online and blended course deliveries across nine terms from 2015 to 2018. Both spring and fall terms last 15 weeks and the summer term is 12 weeks. The courses cover a range of disciplines including Psychology, Spanish, College Algebra, various Computing courses, and Nursing. UCF uses the platform in a variety of different contexts and the student learning in the platform contributes a more significant element of their final grade in some course than others. The data only contains first-time students; repeat students are filtered out.

3.2 Features

It is possible to define a distance metric for the progress trajectories in their raw form and to use the RFC algorithm. However, we can obtain more easily interpretable results for an instructor by extracting features from the trajectories that capture the key behavioral aspects. Through testing and iteration the following six were selected:

Figure 3: The center (mean) of each cluster on each of the key features for the normalized UCF data.

- **Start day** - The first day on which the student made progress.
- **End day** - The last day on which the student made some progress. The day on which the student reached their final % progress value.
- **End % progress** - The percentage of concepts mastered by the student by the end of the course.
- **Num days progress** - The number of days on which the student made progress.
- **Max step** - The single largest jump in progress on a single day.
- **Max days no progress** - Between the start and end day, the largest number of consecutive days on which the student made no progress.

One weakness of the chosen features is that they are only observable after the course is finished making an early prediction of behaviors difficult. Note that the trajectories do not capture all activities completed by the student, just those that increase their progress. For example, practices, revisions, or assessments are not evident in this data.

3.3 Clustering

The RFC algorithm made use of the fuzzy k-means algorithm with the fuzzy parameter set at $m = 2$. Note that the data was normalized before using fuzzy clustering. We set $k_{max} = 10$, $M = 10$, and $tol = 0.05N \approx 250$. The algorithm completed 5 loops and automatically produced 13 clusters in total. The breakdown of clusters per loop and the weight of each cluster is provided in Table 1. We use weight since a student belongs only partially to any one cluster.

Table 1: Cluster and Loop weights W , % and deviation from average δ .

Cluster	W	%	δ	W	Total %	$\bar{\delta}$
C1L1	1685.6	33.42	0.60	3244	64.31	0.57
C2L1	1558.4	30.90	0.55			
C1L2	280.6	5.56	0.29			
C2L2	125.3	2.48	1.25			
C3L2	223.7	4.44	0.38			
C4L2	285.3	5.66	0.87	915	18.14	0.70
C1L3	202.0	4.00	0.61			
C2L3	91.0	1.80	0.75			
C1L4	129.4	2.57	1.12	340	6.74	1.08
C2L4	210.6	4.18	1.04			
C1L5	63.3	1.25	1.29	252	5.00	1.07
C2L5	76.9	1.52	1.52			
C3L5	111.8	2.22	0.44			

The first loop captures the standard approach of applying the fuzzy k-means algorithm once and stopping (if the refinement step is excluded). It is the clusters on loop two to five that are new, and it is here that we find the outlier behaviors that would be missed by the standard approach. Notice that the number of students clustered on each loop generally decreases as the loop count increases. Another point is that these “outliers” account for over 30% of the students.

Figure 3 visualizes the center (mean of the normalized data) of each cluster for each feature. Figure 4 displays the trajectories belonging to each cluster with a membership greater than 0.5. The students with the highest membership values for each cluster are shown in black, and these can be taken as prototypes for each cluster to help interpretation. Note that some of the trajectories in each cluster vary considerably from the prototypes due to the fuzzy nature of the clusters and likely have membership values close to 0.5. The noise present in the clusters on the final loop suggests that perhaps the algorithm stopped too early and allowing additional loops could uncover new behaviors.

From an examination of these graphs, we can see that some outlier behaviors are entirely different from the most common behaviors found on the first loop. There are certain similarities in some cases but enough of a difference to make them worthy of being categorized as separate behaviors.

The clusters found on loop one represent more successful behaviors in that the students generally finish over 50% of the concepts. The first that represents unsuccessful behavior appears on loop two, with more appearing on later loops. Below we provide notes on some of the individual behaviors. A detailed analysis is beyond the scope of this paper.

- Students in cluster 1 on loop 4 (C1L4) master all the concepts in a short period right at the start of the course.
- C2L5 are the students who generally did too little too late.
- C3L5 are students who start well but for some reason stopped with about a month to go.

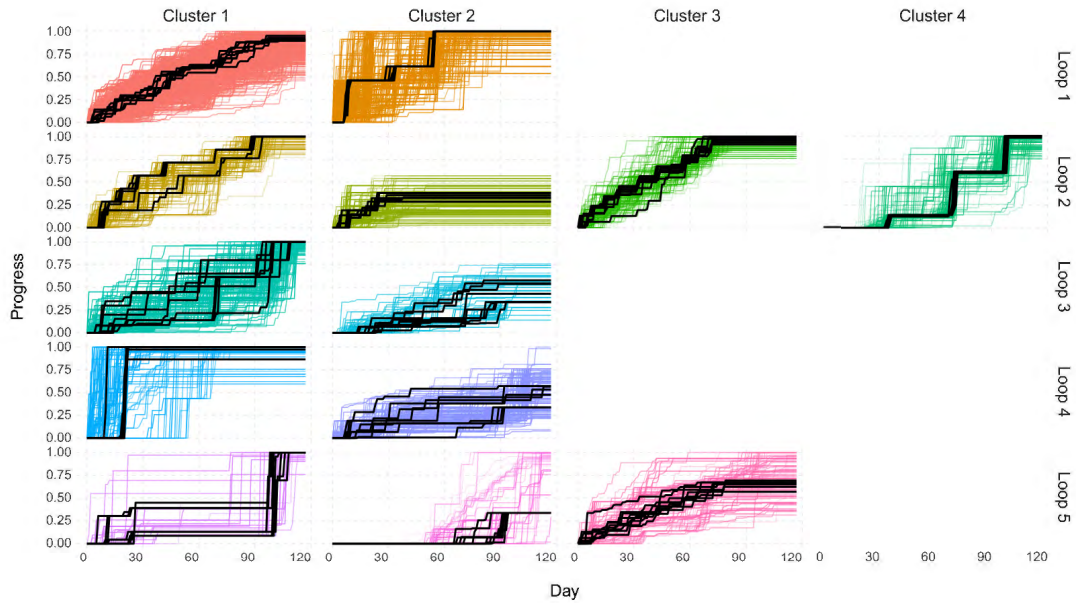

Figure 4: The trajectories belonging to each cluster in the UCF data. The most representative (highest membership values) members of each cluster are shown in black.

- C2L1 and C4L2 are similar in that they make their progress is a small number of large steps. The difference is when in the course that progress takes place.
- C1L5 are students who have a long dormant period in the middle of the course and leave everything to the last minute.

As expected the clusters found on the early loops tend to capture behaviors that are close to the “average,” whereas later loops have clusters that are more different. We demonstrate this by examining the cluster centers displayed in Figure 3. The deviation of a cluster center from the mean (solid black line) is an indication of how far the behavior is from the average. Table 1 provides this deviation, calculated as the mean absolute difference, for each cluster and loop. We see that in general later clusters capture more extreme behaviors. The cluster closest to the average is C1L2, but only represents about 5.5% of the students. The cluster furthest from the average is C2L5 and represents about 1.5% of students. What makes these students stand out is their late start time and low level of progress.

3.4 Comparison

To highlight the limitations of standard approaches, we applied both crisp and fuzzy k-means to the UCF dataset. In summary, these algorithms produce a much smaller number of clusters and do not capture the same range of outlier behavior as those captured by the RFC algorithm. Table 2 display the results from fuzzy k-means for various values of the fuzziness parameter m . For each value of m , the table provides the validity indices, the selected number of cluster k , and the number of outliers based on (2). The value of $m = 2$ is the default and corresponds to applying just one loop of the RFC without refinement. We observe that we get more clusters and fewer outliers as $m \rightarrow 1$. Indeed the validity indices suggest that $m = 1.01$ is the best solution

Table 2: Results of fuzzy k-means for various values of m including the validity indices and number of outliers.

m	k	SIL.F	SIL	PC	PE	MPC	XB	Out.
1.01	5	.58	.58	1.0	.00	1.0	.29	1
1.2	4	.59	.56	.94	.11	.92	.36	66
1.4	3	.58	.51	.83	.31	.75	.46	366
1.6	3	.60	.50	.73	.50	.59	.49	864
1.8	3	.62	.49	.63	.66	.44	.52	1438
2.0	2	.52	.44	.69	.48	.37	.54	1606

of those presented. However, with this solution, we only get five clusters, and these contain high levels of noise and are therefore can be challenging for instructors to interpret. This low number of clusters does not accurately capture the full range of behaviors apparent in the data.

With the solution improving as $m \rightarrow 1$ the logical step to take is to set $m = 1$ and perform simple crisp clustering using the k-means algorithm. We performed this using the NBClust R package [7] which provides a collection of 23 appropriate validity indices to help with the choice of k . Of these, 7 proposed 3 clusters, followed by 5 indices proposing 7 clusters. Both values lead to the same conclusion as we arrived at with fuzzy clustering; that is, the number of clusters does not adequately capture the full range of behaviors.

4. CONCLUSIONS AND FUTURE WORK

The RFC algorithm has allowed us to uncover outlier behaviors that are in some cases very different to the most common behaviors found on loop 1, and in other cases appear visually similar but represent a very different type of learning behavior. The behavioral clusters found here are by no means an exhaustive list. Adjusting the parameters of the algorithm, for example, by changing the parameters

that control the fuzziness of the clustering, would possibly allow more outlier behaviors to emerge.

The purpose of this paper was to describe and demonstrate the RFC algorithm in its current form. Many possible improvements and extensions could be carried out. Once the RFC algorithm has finished, it is possible that clusters on a later loop could better capture a student that belongs to some clusters on an earlier loop. One extension could be to carry out a refinement process moving students from earlier to later clusters. Potentially we can achieve further improvements by including additional features that capture other aspects of behaviors or by applying a weighting to features that are considered more critical.

Lakoff [20] puts the clustering process this way, “Categorization is not to be taken lightly. There is nothing more basic than categorization to our thought, perception, action and speech” ([20] pg. 5). Identifying these student trajectories as either subordinate, superordinate of basic level create a substantial educational responsibility in the adaptive learning environment where students have control time, pace and feedback. If John Carroll [6] was correct in that learning is a function of time spent and time needed then the question is what resources do various student cohorts require. We argue that the clustering process can help in the better understanding of what it will take to help larger numbers of students become successful. As we explore these procedures several questions emerge. If and when will the process become excessively granular and dysfunctional how can these processes be integrated into the educational environment? Can these methods contribute to resolving achievement inequality? Finally, the question remains about whether the clusters exhibit a categorical structure with meaningful prototypes that respond to instructional interventions.

ABSTRACT

Liberal Arts programs are often characterized by their open curriculum. Yet, the abundance of courses available and the highly personalized curriculum are often overwhelming for students who must select courses relevant to their academic interests and suitable to their academic background. This paper presents the course recommender system that we have developed for the Liberal Arts bachelor of the University College Maastricht, the Netherlands. It aims to complement academic advising and help students make better-informed course selections. The system recommends courses whose content best matches the student's academic interests, issues warnings for courses that are too advanced given the student's academic background and, in the latter case, suggests suitable preparatory courses. We base the course recommendations on a topic model fitted on course descriptions, and the warnings on a sparse predictive model for grade based on students' past academic performance and level of academic expertise. Preparatory courses consist of courses whose content has the best preparatory value according to the predictive model. We find that course recommendations are relevant for a wide range of academic interests present in the student population and that students found recommendations for courses at other departments especially helpful. The preparatory courses often lack coherence with the target course and need to be improved.

Keywords

Education, recommender system, warning, topic model, grade prediction.

1. INTRODUCTION

The Bachelor in Liberal Arts offered at the University College Maastricht, the Netherlands, is an honors program characterized by an open curriculum. The program allows students to design their curriculum in a fairly free fashion: more than 75% of the educational credits are free, the college offers over 150 courses covering a wide range of topics from artificial intelligence, to conflict resolution and to pop songs, and students can take up to one year's worth of courses outside of the college. This freedom allows students to tailor their curriculum to their own interests; but the abundance of courses available makes the selection of courses overwhelming. First, the number of courses offered at the

12 departments of the university is too large for students to have an overview of which ones match their academic interests. Second, since each liberal arts student has a unique curriculum, it can be difficult for them to determine if they have covered the necessary prerequisites for a particular course or if the course's level is too advanced given their academic background. A recommender system that suggests courses whose content matches students' academic interests, issues a warning for courses too advanced and, in the latter case, provides suitable preparatory courses would therefore be extremely beneficial. Not only would it increase the students' information position, thereby improving self-advising, but it would also improve academic advising when used as an agenda-setting tool.

Our course recommender system achieves these three goals: course suggestion, warning issuance and preparatory course advice. To receive course suggestions, the student enters her/his academic interests into the system which returns the 20 courses whose content best matches them. In practice, the student selects key words from a predetermined list that represent her/his academic interests. The course recommender system then uses a topic model to identify the courses whose content best matches the topics corresponding to the selected key words (see Figure 1). To receive warnings, students provide their transcript and indicate which courses they are considering for the following term. The system issues a warning for courses that it identifies as too advanced given the student's academic background. In practice, the student enters her/his student ID with which the system extracts her/his past academic performance and the expertise that she/he has acquired in various topics. From these, the system uses a predictive model to estimate the grade that the student will obtain in the selected courses and issues a warning when the predicted grade is a fail (see Figure 2). Each warning issued is then accompanied by a list of preparatory courses whose content has the best preparatory value according to the predictive model.

2. RELATED WORK

Identifying courses that are both of interest to the students and of an appropriate level is a task that has recently gained attention in the literature. Gulzar et al. [8] propose a recommender system that uses information retrieval techniques to select courses based on students' interests. Their system uses key words to search the space of possible courses and tries to improve the quality of the query by finding synonyms and generating N-grams so that the search returns a higher number of courses. Then, they use an ontological model to expand the search even further and retrieve courses related to the previously extracted courses in the ontological model. In this context, an ontological model is a knowledge model that represents relationships between concepts of a previously specified domain, such as 'Computer Science' [7]. This system is content-based since it is the contents of the courses

Raphael Morsomme and Sofia Vazquez Alferez "Content-based Course Recommender System for Liberal Arts Education" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 748 - 753

that are matched to the concepts of the ontological model or the key words of the query. In this manner, the recommender system allows the interest of the students to be matched to the contents of the course. However, the system suffers from several drawbacks: first, the domains (e.g. Computer Science or Medicine) from which the ontological models are built must be defined a-priori [7]. Second, the recommender system is dependent on a well-built database that is not always available at interested institutions.

Figure 2. Warnings and preparatory courses.

Bydžovská [3] develops a recommender system that takes into account a student's past performance and interest profile to make course recommendations. Students' interests are defined in a narrow sense, that is, a course is considered of interest if a student has taken the course or marked it as a favorite in the university system. Course recommendations based on interest are then issued via a collaborative filtering approach: the suggested courses are the courses most selected by other students in the same field of study, or those that were taken by the n-most similar students that already graduated. To detect risk of failure, Bydžovská [3] predicts grades using classification and regression, or nearest neighbor, depending on the course. Warnings are issued after binning the predicted grades into excellent, good, or bad. The main innovation of the system is that it proceeds to include social behavior and take into account courses taught by a favorite teacher or taken by similar students. Although the system attempts to handle both interest and appropriateness of a course's level, it suffers from three major disadvantages: first, it does not provide the kind of transparent recommendation that would allow students to reflect on their course selection because the content of the course is not explicitly taken into account. Second, it does not give students suggestions on how to address their deficiencies.

Third, it does not permit students to change their interest, which is particularly important in a liberal arts context where students go through a broad exploratory phase before specializing.

Bakhshinategh et al. [1] address the issue of recommending courses that help students overcome their deficiencies whilst accounting for changes over time. They view a study program as a path to obtain graduating attributes (skills, qualities, understandings) and rank the impact that each course has on promoting those graduating attributes for a student who took the course. The ranking is done through self-assessment by students after completing the course. The recommender system then uses collaborative filtering to find courses that score highest on promoting a targeted graduating attribute for a student who wishes to develop it further. Thus, if a student lacks "analytical skills", the system identifies courses that improve these skills so that a student comes closer to the level of "analytical skills" that is required for graduation. This system can be used to find preparatory courses for other courses by shifting from graduating attributes to attributes required to succeed in a course. The main disadvantage is that the impact of each course is found through self-assessment rather than in a data-driven way.

Jiang et al. [11] take a different approach to find preparatory courses by using recurrent neural networks to develop a goal-based course recommender. A student specifies a course that they wish to take, along with the grade that they desire to achieve, and the system uses their transcript to find personalized preparatory courses. Although this approach finds preparatory courses in a data-driven way, it does so at the expense of transparency, which makes a student's reflective decision-making process more difficult and provides no direct insight for academic advising.

We use a topic model to extend Bydžovská's [3] use of students' interest. This provides a more flexible and realistic interpretation of a student's interests and how they change over time. Moreover, we use a topic model to expand the search of relevant courses in the manner that by Gulzar et al. [8] use ontological models. The advantage of a topic model is that topics are learned from the data and must not be known in advance. Our system also supplements recommendations with explanations and additional information to help students make well-informed course selections.

3. DATA

We use two types of data: student data and course data.

The student data consists of anonymized course enrollment information. We use the transcripts of the 2,526 students of the liberal arts program between 2008 and 2019 with a total of 79,245 course enrollments. We exclude enrollments with a missing grade which indicates that the student either dropped the course or fail the attendance requirement. In the latter case, the data set contains an observation corresponding to the resit. Table 1 presents the student data. Each row contains an anonymized student ID, a course ID, a year and semester, and the obtained grade.

The course data consists of the 2018-2019 course catalogues of 5 departments of Maastricht University: European Studies, University College Maastricht, University College Venlo, Psychology and Science Program. These catalogues contain a one-page description of 490 courses. Table 2 presents the textual data in the tidy format with one row per document-term [18]. We process the data following common cleaning procedures [13]: we tokenize the individual terms, stem them with the Hunspell dictionary and remove common stop words, numbers between 1 and 1,000, and terms occurring less than 3 times in the data set.

4. METHODOLOGY

4.1 Overview

Figure 3 presents a diagram of the course recommender system. We start by fitting models to the data. We use the Latent Dirichlet Allocation statistical model to fit a topic model on the course data and the lasso penalty to fit a series of sparse multiple linear regression models for grade prediction to the student data. A model is fitted to each course. Their inputs consist of the students' past academic performance and level of expertise in the topics which we derive from their transcript with the topic model.

These models generate intermediate results from the user's input. We use the topic model to infer the student's academic interests from the key words that she/he has entered into the system and the regression models to predict the grades that the student will obtain in the course she/he selected based on her/his transcript.

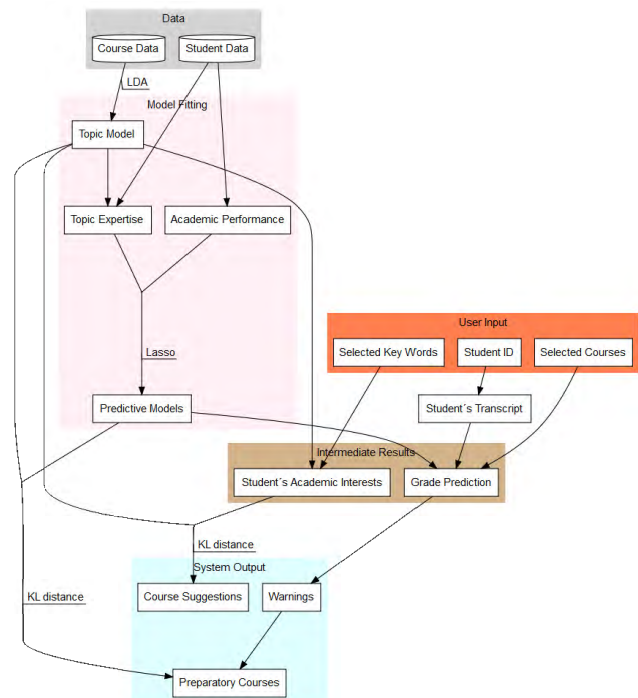

The system's outputs are based on these intermediate results. The course suggestions consist of the 20 courses whose content best matches the student's academic interest in terms of Kullback-Leibler distance. Warnings are issued when the predicted grade is a fail. For each warning issued, we indicate the 5 courses whose content has the best preparatory value according to the regression model. The preparatory value of a course is estimated with the Kullback-Leibler distance of its topic distribution to the coefficient estimates of the topic variables in the linear regression.

All computations are realized on the environment for statistical computing and graphics *R* [16, 13, 10, 4, 19, 20].

4.2 Topic Model

We use the Latent Dirichlet Allocation (LDA) generative probabilistic model and the Gibbs sampling algorithm to fit a topic model to the course data.

The LDA model conceptualizes topics as a probability distribution over a finite set of words (in this case, the vocabulary of the course data), and a document (i.e. a course description) as a sequence of N words, where each word was generated by drawing from a probability distribution over topics specific to that document [2]. Thus, each word belongs to all topics but with different probabilities, and all topics are present in each course but with different weights. Figure 4 and Figure 5 respectively show the word distribution in two topics and the topic distribution in a course based estimated by the topic model fitted on the course data. Technically, the LDA model generates a document as follows. First, the word distribution β for each topic is determined by $\beta \sim \text{Dirichlet}(\delta)$ and the topic weights θ for each document are determined by $\theta \sim \text{Dirichlet}(\alpha)$. Second, each of the N words of the document is chosen by choosing a topic $z \sim \text{Multinomial}(\theta)$ and then choosing a word from a multinomial probability distribution conditioned on the topic z .

**Figure 3. Diagram of the course recommender system.**

Gibbs sampling is a Monte Carlo Markov Chain (MCMC) technique for successively sampling conditional distributions of variables whose distribution over states converges to the true distribution in the long run [5]. Gibbs sampling generates posterior samples by sweeping through each variable and sampling from its conditional distribution when the other variables are fixed to their current values. Phan et al. [14] used Gibbs sampling to learn the distributions β and θ for the LDA model. In this case, δ and α are the prior distributions for Gibbs sampling, acting as hyper-parameters that respectively determine how sparse the distributions of words in topics and topics in documents are. Gibbs sampling picks each word in the vocabulary and estimates the probability of assigning the current word to each topic conditioned on the topic assignments of all other words. With this conditional distribution, given a document, a topic is sampled and assigned as the new topic assignment for the current word. Then, with the distribution of words per topic, we compute the conditional probability of the topics given an observed

document. Since Gibbs sampling is a MCMC, the distribution sampled from a large number of iterations approximates the target distribution [5], enabling us to infer β and θ .

Figure 4. Term distribution in two topics. Topic 4 corresponds to international politics and topic 19 to philosophy.

Figure 5. Topic distribution in the core course COR1004 Political Philosophy. The course is characterized by topic 4 (international politics) and topic 19 (philosophy).

Figure 6. Model selection based on log-likelihood. The maximum-likelihood model has 65 topics.

4.2.1 Model Selection

This procedure requires that we fix *a-priori* the number of topics (k) to be inferred. We trained 30 models with $k = 5, 10, \dots, 150$. We set α to $50/k$ and δ to 0.1 as suggested by Griffiths & Steyvers [6]. For Gibbs sampling, we run 6,000 iterations with a burn in of 1,000 iterations and sample every 100 iterations. To avoid being stuck in a local optimum, we use 10 random initializations to explore the model space and keep the best model with respect to the log-likelihood. We then select the number of topics yielding the model with the largest log-likelihood [6]. Figure 6 shows the log-likelihood of the topic models that we trained. The model with 65 topics has the maximum log likelihood. In order to increase the quality of the selected model, we refit it with more iterations (16,000 iterations with a burn in of 2,000 iterations and 20 random starts; the other parameters are kept the same).

4.3 Warnings

We fit a sparse multiple linear regression model for grade prediction to each of the 132 courses currently offered at the college that have had more than 20 student enrollments since 2008. We regularize the models with the lasso penalty [17]. The set of predictors consists of students' past academic performance and their level of topic expertise at the start of the course. Students' past academic performance consists of 6 variables corresponding to their general and concentration-specific GPA's (humanities, natural sciences, social sciences, skills and projects). Students' topic expertise consists of a set of 65 variables (one per topic of the topic model) which indicate how much knowledge the student has acquired about the topic during her/his studies. A topic expertise variable corresponds to the sum of the topic's importance in the courses taken by the student (as estimated by the topic model) weighted by the grades. We assume that students who obtain 10/10 acquired all the topic-related knowledge present in the course while those obtaining 5/10 acquired half of it. Tables 3a, 3b and 3c and Figure 7 show a toy example of the contribution of individual courses towards a student's topic expertise.

Since the number of predictors is large, we regularize the models with the lasso penalty to increase their accuracy. The lasso penalty shrinks the coefficient estimates of the model, thereby reducing its variance. For each model, we use 10-fold cross-validation (CV) to find the lasso tuning parameter λ that minimizes the CV mean absolute error, a more robust loss function than the squared error [9]. Figure 8 presents the distribution of the CV mean absolute error for the 132 prediction models. The model for the course *PRO2004 Academic Debate* has the smallest prediction error (0.38 grade point) and the model for *SCI3006 Mathematical Modelling* the largest (1.80 grade point). The mean CV error weighted by the number of students enrolled in the course is 0.78, the median is 0.78 and the standard deviation is 0.28.

To receive a warning, the user enters into the system her/his student ID and the list of courses that she/he is considering for the coming term. The system uses the student ID to extract her/his transcript, from which her/his past academic performance and topic expertise are determined. We then use the regression models to predict the grades that the student will obtain in the selected courses and issue a warning for the fail grades (see Figure 2).

4.3.1 Rule-based Warnings

We initially explored an alternative approach for warnings based on association rules. We used the SPADE algorithm [21] to identify sequences in the students transcripts of the type $\langle \text{fail course A} \rangle \Rightarrow \langle \text{fail course B} \rangle$ or $\langle \text{not take course A} \rangle \Rightarrow \langle \text{fail course B} \rangle$ and considered sequences with a support superior to 10 students, a confidence superior to 0.4 and a lift superior to 1.1. Warnings were issued when a student selected a course for which one of the selected rules predicted a failure.

The transparency of this approach motivated its initial adoption; but it turned out to be unsuitable to our case. First, given the small size of the student data and the fact that relatively few students fail courses at the college, only 21 rules met the criteria. Second, this approach ignores the fact that skills necessary to perform well in a particular course can be acquired by taking a *combination* of courses. To tackle the first issue, we considered a relaxed version of the rules that substitutes a $\langle \text{fail course A} \rangle$ with a $\langle \text{obtain less than 6.5 in course A} \rangle$. The number of rules meeting the relaxed criteria increased to 185. Yet, the second issue remained and led us to consider regression models that use topic expertise as a proxy for the skills necessary to perform well in a course.

Table 3a. Toy example: topic distribution in 3 courses

Course	Topic 1	Topic 2	Topic 3	Topic 4	Topic 5
Course 1	0.0	0.7	0.2	0.1	0.0
Course 2	0.2	0.2	0.2	0.2	0.2
Course 3	0.0	0.4	0.2	0.1	0.2

Table 3b. Toy example: transcript

Course	Grade
Course 1	6/10
Course 2	9/10
Course 3	2.5/10

Table 3c. Toy example: course contribution to topic expertise

Course	Topic 1	Topic 2	Topic 3	Topic 4	Topic 5
Course 1	0.00	0.42	0.12	0.060	0.00
Course 2	0.18	0.18	0.18	0.180	0.18
Course 3	0.00	0.10	0.05	0.025	0.05

**Figure 7. Toy example: course contribution to a student's topic expertise. We use these variables to predict grade.****Figure 8. Distribution of the cross-validation mean absolute error in the 148 predictive models.**

4.4 Course Recommendation

To provide course recommendations, we identify courses whose content best matches the academic interests of the students. We use the Kullback-Leibler distance, an asymmetric measure of the difference between two probability distributions [12], to estimate the degree to which a course's topic distribution (as estimated in the topic model) corresponds to the normalized academic interests of the student. The system returns the 20 courses with the smallest such distance. A student's academic interests profile consists of a numeric vector indicating the interest of the student in each of the topics. It corresponds to the sum of the selected key words' contribution to the topics in the topic model. In order to assist students in selecting key words, we preselect the 10 terms most relevant to their topic expertise profile (as defined in section 4.3). To make the system as informative and transparent as possible, each recommendation includes the three selected key words with the most relevance to the course. Here, a term's *relevance*

corresponds to the sum of the term's contribution across the topics weighted by the importance of the topics in the student's academic interests profile or student's topic expertise profile.

4.5 Preparatory Courses

In order to help students plan their curriculum, each warning is accompanied by a list of suitable preparatory courses. Similarly to the regression models built for the warnings, we fit a lasso-regularized multiple linear regression model for grade prediction to each course; but this time, the input only consists of the students' topic expertise. A positive coefficient estimate indicates that more knowledge of the topic is associated with larger grade in the course. For each course, the preparatory courses consist of the 5 courses (excluding advanced courses) whose topic distribution has the smallest KL distance to the course's regression's normalized coefficient estimates.

5. RESULTS

We used expert validation to evaluate the system's usefulness: current students, alumni and members of academic advising interacted with the system and commented on their experience.

We find that the system recommends course that are potentially useful to the students, thereby helping them make better-informed course selections. First, students value the system's ability to consider multiple interpretations of the same term e.g. the term *function* in mathematics and in biology. This feature of the system stems from the possibility for a term to have a large weight in several topics. Second, many users were surprised that they do not need to enter key words present in the course description for the course to be recommended. Since topics act as a buffer between the key words entered in the system and the course descriptions, students merely need to choose key words that characterize topics present in the course. This allows them to focus on their academic interests when selecting key words as opposed to thinking about the courses that might interest them. Third, they found that self-selected key words yield recommendations that are more useful than those stemming from the preselected key words. This pattern is due to the presence of topics related not to the content but the structure of the courses. For instance, topic 25 is dominated by the terms *paper*, *write* and *assessment*. A student's topic expertise profile therefore contains topics related to the *structure* of the courses that they have taken, which, for a student focusing on film art, leads to the preselection of the terms *research*, *method*, *period*, and *skill* along with *film*, *gender*, *literature* and *culture*, and the recommendation of the courses *Research Methods: Interviewing*, *Research skills*, and *Research Project*. Excluding structured-related key words solves the issue and results in suggestions of potentially interesting courses: *Narrative Media*, *Pop songs and poetry*, and *Cultural Studies II*. We therefore include an *opt-out* option to cancel key word preselection. Fourth, students found recommendations for courses at other departments particularly useful: in most cases, they ignored that these courses existed or that their content matched their academic interests.

Students wished that warnings also included low grades. We therefore provide *red* warnings for predicted fail grades ($< 5.5/10$) and *orange* warnings for low ones (between $5.6/10$ and $6.5/10$).

Users were enthusiastic about the preparatory courses; they found it very beneficial to receive suggestions of how to prepare for a particular course. Unfortunately, the preparatory courses returned by the system often lack coherence with the target course. For instance, the list of preparatory courses for the course *World*

History contains the course *Nutritional Neuroscience*. These incongruences may stem from the presence of structure-related topics in the topic model combined with the fact that the lasso penalty shrinks most coefficient estimates to 0. Hence, it is possible that the regression model for grade prediction of some courses only has non-zero coefficient estimates for structure-related topics, hence yielding preparatory courses characterized by these structure-related topics, and not the content-related topics.

6. FUTURE WORK

This course recommender system is a work in progress and the difficulties detailed above indicate three pathways for future work.

First, we need to differentiate structure-related and content-related topics. This seems particularly difficult to do. One approach is to manually inspect the topics that are most prevalent in the corpus of documents and reduce the weight of the structure-related ones.

Second, in order to increase the coherence between preparatory courses and target course, we could impose that their content must be related. The KL distance could be used to accomplish this. We could also take the personalized approach of Jiang et al. [11].

Third, since the topic model has a central place in the system, we plan to improve it by (i) expanding the course data to course manuals (20-page document offering a detailed description of a course's content) and the material covered in the course e.g. academic articles, textbook chapters, and (ii) using a structural topic model that uses covariates to build the model and calibrate topic prevalence and topic content depending on metadata [15] to take into account the origins (department) of the course data.

7. ACKNOWLEDGMENTS

Our thanks to the University College Maastricht, Maastricht University, the Institute of Data Science, and the Department of Data Science and Knowledge Engineering, in particular to Evgueni Smirnov for his technical support and Peter Vermeer for initiating the project and enabling collaboration with the University College Maastricht.

Using a Glicko-based Algorithm to Measure In-Course Learning

reddick@coursera.org

ABSTRACT

One significant challenge in the field of measuring ability is measuring the current ability of a learner while they are learning. Many forms of inference become computationally complex in the presence of time-dependent learner ability, and are not feasible to implement in an online context. In this paper, we demonstrate an approach which can estimate learner skill over time even in the presence of large data sets. We use a rating system derived from the Elo rating system and its relatives, which are commonly used in chess and sports tournaments. A learner's submission of a course assignment is interpreted as a single match. We apply this approach to Coursera's online learning platform, which includes millions of learners who have submitted assignments tens of millions of times in over 3000 courses. We demonstrate that this provides reliable estimates of item difficulty and learner ability. Finally, we address how this scoring framework may be used as a basis for various applications that account for a learner's ability, such as adaptive diagnostic tests and personalized recommendations.

Keywords

Adaptive learning, student modeling, knowledge tracing, student ability estimation

1. INTRODUCTION

A requirement of any adaptive learning system is the simultaneous understanding of learner skill and item difficulty. Such measurements also enable ordering content by measured difficulty and recommending content and assessments appropriate for a learner's degree of skill, among other applications.

Item Response Theory, one common method for obtaining skill estimates in a testing context, requires assuming a fixed skill for the learner. While valid during a single exam, this assumption fails for learners who are learning during a course. Some techniques can rigorously handle

skills that change over time, such as knowledge tracing [2] and performance factor analysis [6], but they are computationally intensive. For Coursera's dataset, applying these techniques would require computing results for millions of learners across thousands of courses. Further, because learners in an online platform can benefit from visibility into their own skills, online updates are desirable. Under these conditions, many approaches become computationally intractable.

To address this problem, we turned to the Elo and related rating systems, which are commonly used in chess tournaments and for team ratings in many sports [7, 9]. Following the example of [7], we treat learners and course items as players in a tournament. Each attempt by a learner at passing an item is a match.

In this paper, we demonstrate the application of the Glicko rating system [3], a variant of the Elo rating system which incorporates uncertainty, to Coursera's unique dataset. We maintain a focus on the most well-measured skills on our platform. We show that we can obtain reasonable and reliable estimates of learner skill and item difficulty. Finally, we discuss planned applications and next steps.

2. BACKGROUND

Coursera is an online learning platform, which offers courses in partnership with the universities and companies that create them. In addition to single courses, Coursera also provides "specializations," which are groupings of 3-10 courses that are usually (but not always) intended to be taken in sequence. Coursera has over 3300 different courses available, covering a broad range of subjects.

Instructors who create courses on Coursera can provide a rough estimate of the difficulty ("beginner", "intermediate", "advanced"), but this is generally not enough to establish prerequisites or help a learner know if they are ready to start a course. Since the label is at the course level, skill-related nuance is lost. For example, a course may teach both intermediate statistics and introductory programming. These labels are also insufficient for a learner to determine whether it would be more valuable to them to jump in to a course or specialization halfway through, rather than start at the beginning. Therefore, it's useful to estimate content difficulty independent of instructor labels. Personalizing this support to individual learners requires estimating their degree of skill as well.

Rachel Reddick "Using a Glicko-based Algorithm to Measure In-Course Learning" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 754 - 759

Many other people have previously estimated content difficulty and learner skill. The most fundamental include approaches based on Item Response Theory (IRT; e.g., [1]). However, these are not suitable in Coursera’s context because they generally assume constant learner skill, as in a testing environment. Although alternatives such as Bayesian knowledge tracing [5] have potential, the methods are difficult to scale up from a few tens of thousands of item attempts to over ten million for a single skill in Coursera’s case. Further, the authors of [5] also note the confounding effect of learners with stronger skills working on more challenging problems, which systematically underestimates the difficulty of advanced content, even in some knowledge tracing approaches.

Therefore, we follow the work of [7] and consider the Elo rating system. The Elo system is commonly used in chess tournaments and other competitions. The general principle is that every player has a score, which is updated after matches. Updates will be large if the outcome of a match is unexpected. If a novice player defeats a master, the novice’s score will have a large increase and the master will have a large decrease. On the other hand, if a master defeats a novice, the updates for both will be small or negligible. This method may be applied to learners and items in courses (such as exams), where each learner and item is interpreted as a player. A new learner who “defeats” a hard item in the Machine Learning skill will gain a large increase to that skill, but not lose much from their score if they fail. Because that ability differs from other skills (such as Management), a learner should have different scores for each possible skill. Items also need to be associated with the relevant skills.

In contrast to [7], we focus on the Glicko variant of the Elo rating system [3]. This variant uses an approximated Bayesian framework, which incorporates uncertainty in the rating. This is particularly helpful for understanding learners who have not yet completed very many items. It also supports estimation of ability across populations by enabling weighted averages based on the uncertainty. The Glicko scoring system has the drawback that it can’t be easily adapted to use more complex IRT solutions, such as those for multiple choice questions with a non-zero success probability even in the case of very low skill. However, because we focus on full assignments rather than individual questions, this will not be a serious limitation.

3. DATA

Coursera has over 38 million registered learners on its platform. We draw our data from late 2014 onward.

We also have a framework for automatically tagging skills to courses. We will focus on those subjects – business, computer science, and data science – where the skills framework is best calibrated. In this two sections, we briefly describe how we tag skills to courses, and how we process the course item data that we use.

3.1 Associating Content with Skills

Based on Wikipedia’s hierarchy of topics and our own human curation, we developed a hierarchy of more than 40,000 skills, over 13,000 of which are tagged to courses in the Coursera catalog (see [8] for additional details). The most

popular of these skills are listed in Table 1, out of a total of 26 available. These broad skills all have a set of subskills within the skill hierarchy.

Individual skills are tagged to courses based on a combination of crowd-sourcing and machine learning. Learners who complete a course are asked to tell us what skills they learned. This information is used as the target variable of a machine-learning model, which estimates the likelihood of tagging based on course content features. The actual tag rate and machine learning prediction are combined to create a single relevance score, giving results for both popular courses and unpopular courses with few crowd-sourced tags.

For our broad skills of interest, we treat a skill as tagged to a course if any of its subskills in the course’s subject area (e.g., data science) are tagged to the course.

Using this approach, for this set of skills, we obtain a total of about 1400 courses tagged with skills. Of these, about 1000 are tagged with more than one skill.

3.2 Item Attempts

We define an item attempt as a learner submission. On the Coursera platform, items include exams with multiple-choice or text answers, programming assignments that require submitting code, and peer review assignments that are graded by other learners. Most, but not all, are graded. In this analysis, we include only items that are graded. Learners are typically able to retake items up to a maximum number of attempts per day.

Learners may retake an item for many reasons, from trying again to technical issues. These repeated attempts are often uninformative. For this reason, we reduce learner attempts to those that are either the first attempt or a later attempt that does not have the same pass/fail outcome. Thus, most learner-item interactions are of the form pass (with no further attempts), fail (with no further attempts), or fail followed by pass at a later time.

This approach has the secondary benefit that if the skill scores are surfaced to learners in the future, there is no longer a motive to repeatedly submit a passed item in order to game the system to get a higher score.

We also remove all attempts at items that all learners pass on the first attempt, since these items are not informative.

We currently do not estimate scores for individual questions or sub-parts within items. Using entire items has the advantage of being able to easily include atypical items, such as programming assignments. Expanding to obtain scores for individual exam questions is left for future work.

4. IMPLEMENTATION

Our implementation of the Glicko scoring system generally followed [3], with several modifications.

Most importantly, the Glicko system assumes that players encounter each other during a tournament, during which individual scores can be assumed to be roughly constant. This is the “rating period” over which matches are accu-

Table 1: Popular Skills

Skill	Number of Attempts	Number of Courses
Statistical Programming	17,840,101	157
Machine Learning	134,52,639	60
Computer Programming	12,940,557	383
Software Engineering	9,287,216	245
Artificial Intelligence	7,900,817	127
Management	6,104,244	386

mulated, and after which an update to the scores is made. However, scores may change rapidly for learners who are learning within a course. Learners watch course lectures or review supplementary material about 40% of the time between subsequent submissions. Therefore, we are forced to use a rating period that is only one “match” long – one item attempt. In this case, the update equations from [3] reduce to, for a single match:

$$\mu' = \mu + \frac{1}{1/\sigma^2 + 1/\delta^2} g(\sigma_o^2) \{s - E(s|\mu, \mu_o, \sigma_o^2)\} \quad (1)$$

$$\sigma'^2 = \left(\frac{1}{\sigma^2} + \frac{1}{\delta^2} \right)^{-1} \quad (2)$$

Where:

$$g(\sigma^2) = \frac{1}{\sqrt{1 + 3\sigma^2/\pi^2}}$$

$$E(s|\mu, \mu_o, \sigma_o^2) = \frac{1}{1 + \exp[-g(\sigma_o)(\mu - \mu_o)]}$$

$$\delta^2 = [g(\sigma_o^2)^2 E(s|\mu, \mu_o, \sigma_o^2) \{1 - E(s|\mu, \mu_o, \sigma_o^2)\}]^{-1}$$

In these expressions, μ is the initial score, μ' is the updated score, σ is the initial uncertainty in terms of standard deviation, and σ' is the updated uncertainty. The values with a subscript ‘o’ are those for the opponent. If the “player” is a learner, then the opponent is an item (and vice versa). s is the outcome of the match. For a learner, passing the item is a ‘win’, and $s = 1$, and failing is a loss with $s = 0$. The reverse is true for items.

Our difficulty scores for items are based entirely on the scoring method described above. Instructor provided difficulty labels were not used as a feature in this framework.

Importantly, the learner’s score carries over from one course to another, so long as both courses teach the same skill. For example, when a learner finishes a course and starts another, their score for the skill at the end of that course is used as their starting point for that skill in the new course. If the courses teach different skills, then the learner’s score for the new skill taught in the second course will start at zero, unaffected by their score in previously learned skills.

Finally, to obtain high-quality scores for all learners, we find that we need to run the Glicko scorer twice. In the first run, we set both learners and items to have prior scores of 0

Figure 1: Scores for course items generally converge after many attempts. This example shows several items from the Practical Reinforcement Learning course, in the Machine Learning skill. The item scores rapidly converge to stable values, with a small amount of negative drift. For clarity, we only show the first few items in the course.

and uncertainties of 5, to allow large updates initially and to prevent questions with well-established scores to avoid experiencing large perturbations from new learners. This provides good estimates of item difficulty, but means that learners who took the same item early in the data, rather than late, are matched up against items whose scores may be far from reasonable values, especially for less popular content. It also means that a learner who has completed the same course, but early in our data, may not have the same score as a learner who performed in exactly the same way in the same course near the end.

Thus, all learner scores are reported based on the Glicko scorer a second time, using the item scores and uncertainties from the first run. These values for items are held fixed. The items scores for each skill are offset so that the fifth percentile item has a score of zero. Learners start with prior scores of zero and prior uncertainty of 1.0, which avoids excessive initial swings in score.

In principle, it is possible to construct a more accurate learner prior score based on information they have given us (e.g., education history) and what course they are starting. However, this could also lead to gaming of the system (by providing false information or trying a hard course first to obtain a better score), may be biased against learners with nontraditional backgrounds, and introduces additional complexity.

Figure 2: Comparison of final item scores within a single course (in the Machine Learning skill). As expected, later items are generally more difficult than earlier ones. The method also successfully captures differences in difficulty among different types of items – graded programming assignments tend to be more challenging than exams.

5. RESULTS

We show the convergence results for a few items in a typical course in Fig. 1. This is the Practical Reinforcement Learning course, within the Machine Learning skill. As we might expect, items later in the course are typically more challenging, but not always. This reflects variation in difficulty of sub-topics within the course.

Although the item scores clearly converge within the first few hundred attempts, there is also a long-term negative drift in the scores. This is a known occurrence within Elo frameworks (for examples in chess, see [4, 10]). In the case of chess, players generally begin playing as novices and stop playing as masters, with a higher skill than they started. The pressure of new players always starting with low scores leads to ratings deflation over time, and chess tournament rating systems often include corrective factors for this reason. In our case, a similar effect occurs because learners generally start with lower scores than those of the items.

The degree of drift over a few hundred attempts is typically of the same order as the estimated uncertainty (around 0.2 for the first item in the example course). In the future, we may add a correction for this drift effect, but it does not currently have a strong effect on our results.

For clarity, we note that convergence is only expected or desirable for item scores. Items within courses are generally not modified over time, and therefore, the difficulty of the item should not change. In contrast, learner scores can be expected to change rapidly as they progress through course content.

When we examine the final item scores more closely, we find that there are some differences by item type. Programming assignments are often more difficult than regular exams (see Fig. 2), in agreement with our expectations for these items.

Even with this variation and within-topic variability, we find that difficulty does generally increase from the beginning to

Figure 3: Histogram showing the distribution of the correlation between item difficulty and item order for each course in the Machine Learning skill. Extreme correlation (or anti-correlation) generally comes from courses with few items.

Figure 4: learner score while progressing through a course. This plot shows a learner progressing through a Machine Learning course, and completing it. Note the occasional small drop in score when the learner initially fails an item. Error bars are $\pm 1\sigma$.

end of a course. Across all skills, the mean correlation between item order and item difficulty within a course is 0.25. The distribution of correlations for a single skill, Machine Learning, is shown in Fig. 3.

We also find that scores across different courses make sense. For example, based on median item score within the Machine Learning skill, the “Google Cloud Platform Big Data and Machine Learning Fundamentals” course is the easiest. This is the first course in a sequence of courses which are intended to be introductory. Conversely, the hardest course is “Probabilistic Graphical Models 3: Learning”, the final course in a series of advanced Machine Learning courses.

A representative example of a learner gaining the Machine Learning skill is shown in Fig. 4. The learner rapidly increases in score to match the initial difficulty of the course, followed by more incremental increases later on. This is

Figure 5: A profile showing the top 5 most relevant skills for a data scientist and the typical degree of proficiency. In this example, the skill score is shown as a percentile compared to the rest of the learners on Coursera.

fairly typical of learners moving through a single course.

6. FUTURE APPLICATIONS

These difficulty and ability scores, in combination with our skills tagging framework, unlocks many applications:

1. **Learner skill profiles.** These surface a summary of each learner's measured abilities. Providing this information to learners would enable them to better understand their own skills and how much they have learned so far. These profiles would update online to immediately reflect recently submitted items.
2. **Career skill profiles.** In contrast to a learner skill profile, a career skill profile shows the skills important to a career and the necessary degree of proficiency. These profiles can be built based on the skills of learners on Coursera who are already in these careers. Then these profiles can be compared against a learner profile, to allow the learner to see what they still need to enter their desired career.
3. **Recommendations by difficulty.** Given knowledge of a learner's current and desired ability in a skill, we can recommend courses that teach that skill which are at the right level for that individual.
4. **Adaptive diagnostics.** With difficulty scores for course items, it is possible to extract questions from course content and use them as the question bank for an adaptive diagnostic, which provides questions close to a test taker's estimated skill. If learners take diagnostics as a pre-test, before taking any courses, this can support the recommendations by difficulty discussed above.
5. **Review recommendations.** If a learner struggles in part of a course, a recommendation to review could find lectures or reading, potentially in another course entirely, which teaches the same skill at an easier difficulty.

We show an early example of a career skill profile for a Data Scientist in Fig. 5. These initial results align with our expectations, in that more fundamental skills for the career

(e.g., Machine Learning) are required at a higher relative skill than the more niche skill of Artificial Intelligence.

We would expect this approach to generalize well to other data sets, if the fundamental data can be constructed as attempts by learners at passing items.

For simplicity, our current approach omits the addition of uncertainty for time passed since the last scoring update. In the original Glicko model, this incorporates how a player's skills may have increased due to practice or decayed due to lack of use over time. In the future, it may be valuable to restore this factor, with additional uncertainty for learners who have spent a significant time perusing course material, or who have spent a long period away from course content.

Similarly, this approach ignores cases where multiple skills are related or relevant. For example, Machine Learning and Artificial Intelligence are closely related. However, because we treat each skill in isolation, a learner who has only taken courses in Machine Learning will not have an estimated score for Artificial Intelligence. Similarly, an item in a course may require more than one skill to pass the item. In future work, we will consider multiple-skill approaches that can address these cases.

7. CONCLUSIONS

In sum, we find that using the Glicko rating system in an educational context produces reasonable scores for learners and items. The approach successfully mitigates the potential bias from more skilled learners encountering more difficult items.

We plan to use these results in many applications in the future to improve the learning experience for learners on Coursera.

8. ACKNOWLEDGMENTS

I would like to thank my colleagues, Vinod Bakthavachalam and Alan Hickey for providing valuable input on the methods and feedback on the contents of this paper. I would also like to thank Emily Sands for her feedback and support.

Affect detection in home-based educational software for young children

ABSTRACT

Research on automated affect detection in educational software using play log data has shown promising results. Yet most studies use classroom-based software designed for adolescents or adults. In this paper, we aim to detect affection in an online educational platform primarily aimed at home use by young children. This presents two challenges: we have to rely on a self-report instrument of affect that users can utilize at home, and we have to make sure that this instrument is properly understood by children. To this end, we developed and validated an emoticon-based self-report instrument to derive ground-truth labels of four emotions: Joy, frustration, confusion, and boredom. Training a number of different classifiers for automated affect detection yields promising results, in particular for detecting joy and frustration.

1. INTRODUCTION

It is by now well established that student engagement is an important correlate of learning efficacy, academic performance, and even long-term professional achievements [1, 2]. Consequently, monitoring student engagement is of key interest, so that appropriate interventions can be applied when necessary. Educational software holds a strong promise in this regard, as it enables the collection of troves of data that can be mined for engagement and learning patterns.

Previous research has demonstrated that student engagement is a multifaceted concept, typically encompassing behavioral, cognitive, and emotional aspects [5–7, 14]. There is a large body of empirical literature that aims to identify these facets of engagement during educational software use. Emotional engagement – or affect detection – in particular has garnered a lot of recent interest. Previous studies in this area have collected data from sensors and play logs to construct and identify metrics that can detect different types of emotions (and changes therein) [1, 3–5, 12].

Our objective in the current paper is to explore the possibility for affect detection based on play logs in a particular

online learning platform, called Scula. This platform embodies two traits that inhibit a straightforward application of previous research. First, Scula is primarily developed for use at home, whereas virtually all previous research considers educational software used in the classroom. Second, Scula is used by children aged 4-12, whereas previous studies mostly consider adolescents or adults.

In order to train models for automated affect detection, we first have to collect instances (i.e. ‘ground truth labels’) of students’ emotions during software use. Ideally, these data are collected during normal use of the product, i.e. when students play at home. This in turn requires a self-report instrument that can be understood and used by children. In particular, the instrument should take into account that young children cannot read, and that identifying their own emotions might be problematic.

To address these issues, we first design and validate a self-report instrument of affect that is based on emoticons. In particular, we aim to identify four emotions: Joy, boredom, confusion, and frustration [1, 3]. We then use this instrument to collect ground truth labels of affect during software use. Finally, we construct a number of features from the play logs and correlate these with the labeled emotions, building four separate affect detectors (one for each emotion).

2. THE ONLINE LEARNING PLATFORM

The software used in this study is an online educational gaming platform for K-6 children (ages 4-12) in the Netherlands, called Scula. Scula’s primary business model is aimed at home-use, i.e. paid subscriptions are sold to parents. The platform is available through web as well as via a native app (iOS and Android). It is set up primarily along 8 education classes that correspond with the grades in kindergarten (KDG), pre-school (pre-K), and elementary school. Children can play a variety of subjects, both curriculum based (e.g. math or spelling) as well as outside the curriculum (e.g. social skills or 21st century skill).

Within a subject, students can choose a topic, within which they can choose a mission, that itself is typically subdivided into multiple (hierarchical) levels.¹ One level typically consists of ten questions that have to be answered correctly be-

¹For example, grade 3 has the subject geography, containing the topic ‘weather’, which has two missions. The first is ‘seasons’, consisting of five levels, and the second is an instruction video about rain.

Roger Smeets, Francette Broekman and Eric Bouwers "Affect detection in home-based educational software for young children" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 760 - 765

fore the level is completed and the next one is unlocked. Importantly, students have complete freedom regarding what to play. The only restriction is that within a mission, levels have to be played in a predetermined order.

There are various different question formats, such as multiple choice questions, puzzles, open-answer questions, bubble poppers (popping foam bubbles containing answers), and catapult questions (shoot at answers with a catapult). If a question is answered incorrectly, the right answer is highlighted, and the question is moved to the end of the queue, so that the user has to answer it again after cycling through the remaining questions. At any point during playtime, a user can choose to quit the current level. She can always go back to that level and pick up where she left off.

When answering a question correctly, the user is rewarded with a coin. There are also numerous ways to earn bonus coins, e.g. when participating in a thematic campaign. Coins can be used to buy new avatars, or non-digital goodies from the goodie shop (e.g. cinema vouchers, toy-store vouchers, or paper-cut animals). During play, users also collect experience points, which gradually increases their experience level. Each experience level unlocks new benefits, such as new avatars in the avatar shop.

When users log onto the platform, they land on the home screen depicted in Figure 1. Here, they can navigate between the different subjects, but also to their playing statistics, to the Scula shop – where they can buy avatars and goodies with the collected coins – and to the ‘social’ screen – where they can search for friends, send and accept friend requests, and send or read messages to and from friends and parents. The top of the screen shows their experience level, their experience points, and the number of coins collected. Finally, the home screen also offers play recommendations in the three tiles in the top bar.

3. PREVIOUS RESEARCH

3.1 Log-based affect detection

Previous research on automated affect detection has used both sensor data and play log-based data to find correlates of affect. The educational software used in this study does not utilize sensors, so that we have to rely on the latter approach. Below we briefly review a number of studies that have successfully done so before.

In a study involving an automated tutoring system, D’mello et al. [5] use a combination of conversation-based log metrics and self and third-person reports – by one peer and two expert judges – of affective states. Their results show that machine predictions of affect are on par with those of ‘novice’ judges (self and peer) but inferior to those of the trained judges.

Contati and MacLaren [4] and Sabourin et al. [12] adopt a (dynamic) Bayesian network approach to develop a causal model linking user goals and (inter)actions to affective states. The resulting models significantly outperform default class prediction, and further allow the researchers to infer user play-goals.

Figure 1: Scula home screen (web)

Lee et al. [8] show that persistent confusion negatively correlates with learning achievement, yet that resolved confusion has a positive effect. Botelho et al. [3] resort to Recurrent Neural Networks to improve the performance of these models. Unlike previous studies, they combine all emotions in one detector, rather than training one detector per emotion.

3.2 Affect detection for young children

All the studies discussed above share two traits: First, they all involve educational software that is used in a classroom setting, and second, the study populations are usually either adolescents or adults. Yet in this paper we consider educational software designed for home use by children. This means that collecting data in a controlled setting – such as a classroom or lab – would interfere too much with the intended user experience. As a result, affect labeling has to happen at home, using self-reports. Yet this creates another challenge, which is that (young) children cannot be expected to provide reliable survey feedback [9].

A number of studies have developed instruments for usability testing of software products with children [10, 11]. This research stream restricts the notion of child engagement or satisfaction to “fun”. One validated instrument that has been successfully applied in this context is the *smiley-o-meter*. This is essentially a 5-point Likert scale with emoticons capturing the intensity of fun (vs lack of fun).

However, Padilla-Zea et al. [13] find that this instrument is not properly understood by young children (ages 3-5), since they are not able to grade the strength or intensity of a feeling. Yet their tests demonstrate that young children *are* able to differentiate between different *types* of emotions, based on different emoticons.

Our approach toward affect labeling mirrors that of Padilla-Zea et al.[13]: Instead of aiming to capture the *intensity* of one emotion, we want students to identify the relevant *type* out of several emotions. To this end, we develop an emoticon-based instrument, while taking into account that the youngest respondents cannot read.

Following Baker et al. [1] and Botelho et al. [3], we aim to capture four affective states: Joy, confusion, frustration,

and boredom.² However, before putting the emoticon-based instrument to use, we first have to ensure that we design a set of emoticons whose meaning is understood by the students. This design and validation process is described in the next section. Section 5 then discusses our initial efforts towards automated affect detection, using this instrument to collect ground-truth labels.

4. AFFECT INSTRUMENT VALIDATION

4.1 Method

We first designed six sets of three emoticons, or 18 in total. The emoticons in the first four sets were designed to capture joy, confusion, frustration, and boredom. We added two more sets to represent surprise and sadness. We then proceeded in three steps.

In step one (the offline adult test), we presented each of the six sets to 14 adults, asking them (1) to express the emotion they inferred from each of the 18 emoticons, and (2) to choose the emoticon (out of three) they found most fitting for each of the six emotions. Achieving consistency across feedback from adults served as a lower threshold in this case. Eventually, this step resulted in six emoticons preferred by adults, one for each affect type.

In step two (the offline child test), we presented these six emoticons to 23 children aged 4-12 in one-on-one sessions, asking them (1) to express the emotion they inferred from each of them, and (2) to choose the emoticon (out of six) they found most fitting for a particular scenario. This step was intended to flag potential interpretation differences between adults and children, allowing for a redesign if necessary. Eventually, this step resulted in a set of emoticons preferred by children.

In step three (the online child test), we used the emoticons from step two to develop a new online ‘affect mission’ with two levels on the Ssula platform. In the first level, children were presented each of the emoticons individually, while being asked to answer the following question: “Look at the character in the picture. What do you see?” They were then offered four answer options, one of which contained the intended meaning of the emoticon.³

In the second level of the mission, users were asked questions of the type “Which of the characters is [...]?” where [...] was substituted for a particular emotion. They were then shown five emoticons, one of which contained the one we intended to actually capture the emotion. For children aged

²To be precise, these studies aim to capture “engaged concentration” rather than “joy”. However, in designing the instrument we ran into difficulties capturing the former. Instead, we opted for “joy” as a substitute positive affective state that is more easily understood by children.

³An alternative setup would have been to ask children open-answer questions. However, since our youngest users are not able to write, this option is unfeasible. Furthermore, our experience with these types of questions is that many children abuse this freedom of answering by providing nonsensical or offensive answers, increasing the effort of identifying relevant answers. Nonetheless, we attempted to ensure that one or two of the alternative answer options served as detractors.

Table 1: Respondents by grade level

Grade level	# Respondents	Respondent share
KDG	1169	5.4
Pre-K	1972	9.1
Grade 1	2965	13.7
Grade 2	2421	11.1
Grade 3	3222	14.8
Grade 4	3411	15.7
Grade 5	3570	16.4
Grade 6	2985	13.7

Figure 2: Initial confusion emoticon

4-7 we provided voice-recordings of both the question (in both levels), as well as the answer options (in level one).

The two mission levels were live on the platform for one week (from November 19th 2018 to November 26th 2018). During that time period, we collected responses from 21715 unique players. Table 1 shows the distribution of respondents by grade level. Although respondent shares are notably lower in the bottom two grades, they are representative of the user population across grades.

4.2 Results

The offline adult test resulted in one emoticon per affective state that was preferred by adults. In the offline child test, the emoticons for joy and boredom were correctly interpreted by children. The same holds for frustration, although most children identified this as anger instead. However, given their relatedness, as well as the fact that young children are generally not familiar yet with the notion of frustration, we deem these as interchangeable.

However, confusion was not well identified. Figure 2 depicts the original emoticon that was used. When asked what the character was feeling, typical responses were ‘nauseous’, ‘funny’, and ‘dizzy’. Further probing revealed that both the wiggly mouth as well as the cross eyes confused children’s interpretation regarding the intended meaning.

We used this feedback to redesign the confusion emoticon. In particular, two new designs were made. Additionally, we also designed an additional emoticon for frustration, in order to verify that the response ‘angry’ was not driven by the emoticon but rather by children’s lack of awareness of the concept of frustration.

All in all, we ended up with a set of eight emoticons, pre-

Figure 3: Final test emoticons

sented in Figure 3: Joy (A), thoughtfulness (B), confusion (C), anger (D), frustration (E), boredom (F), sadness (G), and surprise (H). Recall that we are primarily interested in capturing joy, confusion, frustration, and boredom. We had two emoticons for confusion (B and C) and frustration (D and E). We used the results of the online child tests to choose the preferred/optimal one. The emoticons for surprise and sadness were used as additional detractors in the online child test.

Using the data from the online child test, we compare the share of respondents that chose a particular answer option. Chi-squared tests show that the distribution of response shares on all questions in all grade levels are significantly different from uniform, indicating that *at least* one answer received a disproportionate share of responses. Computing Chi-squared statistics on all answer pairs per question reveals there is only one instance where *two* answer options are equally preferred: This concerns the level one question regarding the confused emoticon (C) in kindergarten.

The four answer options presented to users in this case are ‘struggling’, ‘confused’, ‘surprised’, and ‘sad’, with ‘struggling’ added as a detractor. Indeed, in Kindergarten the detractor received a sufficient number of responses so as to not be statistically differentiable from the ‘confused’ answer option. Yet for present purposes, the distinction between struggling and confused is negligible. Both these emotions correspond to what we aim to capture, which is that the user is having difficulties understanding or answering questions.

In all of the other cases, the preferred answer option corresponds to the intended answer option. The degree of variation across answer options is notably higher in the lower grades. Figure 4 illustrates this. It shows the response shares across the five emoticon options for the question ‘Which character is bored?’ Although the bored emoticon (F) receives the highest response shares in all grades, the variation is notably greater in the bottom two grades, with the angry emoticon (D) as a close second.

Finally, the online child test also enables us to identify the preferred emoticon for confusion and frustration. In all grades, emoticon C is preferred for confusion, and emoticon E is preferred for frustration. An added benefit is that the primary detractor for Kindergarten and Pre-K, i.e. emoticon D, is not part of the final set.

Table 2: Answer response shares per trigger

Answer	Level completed	Level interrupted	Navigating
happy	54.4	28.5*	33.2*
bored	15.4	14.8	11.9*
confused	9.6	9.7	6.7*
frustrated	9.5	18*	8.8
not-answered	11.1	29.1*	39.5*

* Response share different from quiz-completed ($p < 0.05$)

5. AFFECT DETECTION

5.1 Method

Using emoticons A, C, E, and F in Figure 3, we designed a modal to prompt users for feedback regarding their affective state during playtime. Since we are targeting young children whose parents pay for the product, we did not want to excessively disrupt their play experience. We therefore present the modal following three specific triggers (with a maximum of three modals per week):

1. When a user finishes a mission-level in one attempt
2. When a user prematurely interrupts a mission-level for the first time
3. When a user has been navigating the platform without playing a mission-level for three consecutive minutes

In all three cases, users are shown a modal that prompts them for their affective state. Their response is logged, together with the relevant trigger, a timestamp, an id of the particular gamesession⁴ that they are playing (in case of the first two triggers), or the url that they were visiting when they were shown the modal (in case of the third trigger). Users have the option to close the modal without providing an answer, which is logged as well.

In Section 5.2, we first compare the affect response distribution following the first trigger with that following the other two. The first trigger serves as the benchmark case: We expect that users are predominantly happy when they finish a mission-level, and that the two other triggers typically correlate more strongly with a lack of enjoyment.

In Section 5.3, we then present the results for four affect detectors (one for each affect state) for users playing the subject *math*. We construct 51 mission-level features (such as the share of correct questions, the total number of questions answered, or the minimum, median, maximum and standard deviation of answer time per question) to serve as inputs, with the collected affect responses serving as outputs. We trained the following models (hyper parameters within parentheses):

- Logistic regression with elastic-net regularization (mixing parameter between L1 and L2 regularization, and regularization weight parameter) [glmnet]

⁴A gamesession is a particular play instance of a mission-level by a student.

Figure 4: Which character is bored? (intended answer in orange)

- C5.0 classification tree with boosting (tree vs rule-based model, number of boosting iterations, and without or without feature selection) [**C5.0**]
- Naive Bayes classifier (Laplace correction and bandwidth adjustment) [**nb**]
- Random forest (the number of selected features to try during bagging) [**rf**]
- Gradient boosting machine (number of boosting iterations and maximum tree depth) [**gbm**]

Table 3: Model training results

Affect state	Model	Kappa	AUC
happy	gbm	0.212	0.643
bored	C5.0	0.051	0.541
confused	rf	0.077	0.617
frustrated	glmnet	0.173	0.669

Following Baker et al. we use 5-fold student level cross-validation to guide hyper-parameter tuning of the model, and conduct down-sampling to achieve response balance during cross-validation [1]. In terms of hyperparameters, we perform grid searches to determine the optimal parameters during cross-validation, and use the optimal model to compute performance on the (held out) test set. The objective metric for model training is Kappa.

5.2 Trigger comparisons

Table 2 presents the share of responses per answer-type and per trigger. In all three cases, the dominant answer option is ‘happy’. Yet the share is notably higher when users complete a level than when they interrupt it or when they are navigating. Conversely, the share of frustrated users is notably higher when a level is interrupted. There is little difference in boredom and confusion between completing and interrupting a level, however. Finally, players are much more likely to ignore the modal when they are navigating or after they interrupt a level, compared to when they complete a level.

It is noteworthy that a non-negligible share of users chooses to ignore the modal, in particular when interrupting a level or after navigating for a while. Given the difference with the ‘level completed’ share on this response, this *could* be indicative of a lack of enjoyment as well, yet without more detailed user feedback this is impossible to verify.

These patterns are by and large replicated across grades and subjects (for the level completed and interrupted triggers).

The most notable differences are that players in kindergarten and pre-school (1) more often choose to ignore the modal (regardless of the trigger), and (2) are less frustrated when interrupting a mission-level.

5.3 Affect detectors

Table 3 presents the model results in terms of Kappa and AUC.⁵ The detector for boredom is weakest, followed by that for frustration, confusion, and boredom, respectively. This partly reinforces the results presented in Table 2, where we observed that happiness and frustration exhibit most variation between the level completed and interrupted triggers.

Table 4 shows the top-3 features per detector. The share of correctly answered questions appears in three of the four detectors. This is also true for the response time between the moment the modal is shown, and when it is answered. Finally, note that *happy* and *frustrated* share two of the top-three features. This could indicate that these two emotions are two sides of the same coin.

6. DISCUSSION & CONCLUSION

In this paper we have developed and validated an instrument for affect detection that can be used during home-based educational software use by (young) children. Consistent with previous research, we find that children aged 4-12 are able to

⁵The model performance statistics reported in Table 3 are based on a test set with the original, non-resampled response distributions. The test data are again completely disjoint from the training data at the student

Table 4: Top-3 model features

happy	share of correctly answered questions response time to modal trigger that generates the modal
bored	player grade level share of correctly answered questions a repetitive streak of calculator questions
confused	response time to modal the type of questions that was answered last the average difficulty of questions in the level
frustrated	the difference between user performance and average question difficulty share of correctly answered questions response time to modal

differentiate between four different affective states (joy, boredom, confusion, and frustration) based on a set of emoticons.

We find that users in our study that complete a mission-level are predominantly happy, whereas those that interrupt it are predominantly unhappy. Furthermore, this unhappiness mostly reveals itself as frustration. For users that have been navigating for an extended period of time, the conclusion are less clear, in particular given the high share of users which ignore the modal.

In comparison to existing studies on affect detection in educational software, we find that the response distribution across affect states – reported in Table 2 – is much less skewed. For example, Baker et al. (2012) find that close to 85% of their responses capture engaged concentration, and just 0.9% confusion [1]. The differences with the results reported in this study could be driven by a variety of factors, most notably the fact that our target population includes children instead of adults/adolescents, and the fact that students are playing at home rather than in the classroom. More generally, recall that students are completely free to pick and choose what they play on the platform. This is very different from many of the previous studies, where software is used in the classroom and as part of the curriculum, including instruction. At the very least, it illustrates that the findings in this literature cannot simply be extended to other contexts.

Compared to Baker et al. [1], the performance of our automated affect detectors is quite a bit weaker. In part, these differences might be driven by the different number of model features (51 vs 258) and in target populations, i.e. children vs adolescents. Yet another explanation might be that our emoticons leave more room for interpretation differences than text surveys. As a result, out affect identification might be less precise than in earlier studies.

Going forward, the ultimate goal is to be able to detect affect during playtime, in order to provide meaningful and effective interventions. The processes and results reported in this paper are a first step towards that goal. The best performing models are still weaker than those found in previous research. However, the models for detecting joy and frustration perform notably better than chance. This suggests that it is worthwhile to put more effort into feature construction and

algorithm selection for these detectors.

ABSTRACT

Advances in the tutoring systems present a unique opportunity for effective and cost-efficient tutoring for the students. Such tutoring systems produce a large amount of educational data. Therefore, there is a growing need for data-driven learning techniques applicable to the development of Intelligent Tutoring Systems (ITSs)[4, 7, 18]. One of the goals of ITSs is to improve the traditional education methods by providing individualized tutoring for every student, from underrepresented ones to those with high competency level.

Reinforcement Learning (RL)[20] provides a data-driven approach to personalize the learning environment for each student in a cost and time effective way [11, 13]. Such an inexpensive, personalized and data-driven approach provides an opportunity for every student based on their level of competency [23]. However, several major challenges need to be addressed for the induction of an effective RL policy. For example, one of the major challenges lies in the definition of the states, actions, and rewards in the educational domain. It is known to the community that the data collected by the tutoring systems is usually noisy, and the rewards, such as learning gain, are only available with a significant amount of delay. When the immediate reward is not observable, inducing an effectiveness offline RL policy is challenging. One example of this is when we measure the performance of students in the exam they take at the end of the semester. On top of that, there are several sources of uncertainty in educational training data. For example, the student's learning state is not completely observable. At the same time, the student's interaction with the tutoring system is not deterministic which makes the training data noisy. In this

workshop, we discuss the issues to induce effective policies for educational purposes in the presence of uncertainty and delayed rewards.

1. INTRODUCTION

Since successful cases of data-driven approaches in ITS have increased substantially in the past years[2, 17], there is a growing need for researchers to share the new methods and present their work.

This workshop will provide the opportunity for researchers to 1) present their negative as well as positive results in order to learn from past experiments, 2) present and discuss the state-of-the-art techniques in RL, 3) expand the community of researchers interested in the field. In this workshop, we present full and short papers, as well as posters concerned with the application of RL in education. The research includes diverse issues in RL for ITSs such as representing learning states, defining reward functions, discovering effective actions, and introducing new ITS environments. Specifically, we cover a variety of RL topics including but not limited to:

- Tabular Reinforcement Learning[12, 3]
 - Markov Decision Processes (MDP)
 - Partially Observable MDP (POMDP)
 - Monte Carlo Simulation (MCS)
- Reinforcement Learning with approximation[19]
 - Model-based and model-free methods
 - Off-policy and on-policy methods
 - Q-learning
 - Policy Gradient algorithms
 - Actor-Critic algorithms
- Offline Policy Evaluation (Importance Sampling and variants)[21]

2. RL FOR EDUCATIONAL DATA MINING 2019

RL for Educational Data Mining workshop will be held within the Educational Data Mining 2019 conference in Montreal, Canada. This workshop will be organized as a half-day mini-conference. We will start the workshop with a presentation about two ITSs developed at the Department of Computer Science at North Carolina State University. Then, we will present our recent work about the challenges of applying Deep Reinforcement Learning (DQN) [10] for Pedagogical Policy Induction. These challenges include 1) reward reshaping [1] and inferring immediate rewards from delayed rewards to induce effective pedagogical policies, 2) offline evaluation of the induced pedagogical policies [6, 9] and 3) discussion about different deep reinforcement learning algorithms and architectures such as Double DQN [22] and Double-DQN with prioritized experience replay [14], Actor-Critic methods [15, 16], Deep Deterministic Policy Gradient (DDPG) [8] and Soft Actor-Critic (SAC) [5]. Next, we will dedicate our time for the full paper presentations and discussions after each presentation. We will continue with networking and planning for future works and collaborations.

During this mini-conference, we will transfer the required knowledge to understand the best practices for conducting research with RL for Educational Data Mining. Moreover, we will discuss the challenges, limits, and future directions of RL for Educational Data Mining.

3. ACKNOWLEDGMENTS

This workshop was supported by the NSF Grants: #1522107, #1651909, #1660878 and #1726550.

ABSTRACT

This workshop is the second edition of LABBEC 2018 [2]. It aims to foster the exchange of ideas between the field of education measurements and education practitioners, and the EDM community. Research contributions were invited on topics related to the mutual influence between EDM and the education community. Demos of real world applications issued from EDM were presented and a discussion in the form of a round-table closed the workshop.

Keywords

Psychometrics, Educational measurements, Education settings

1. INTRODUCTION

Spawning from computer science, the Educational Data Mining (EDM) and Learning Analytics (LA) fields have generated a wealth of research over the last decade, including two yearly conferences and two scientific journals. EDM and LA typically aim to discover relations of interest by analyzing institutional or digital learning environment databases. Often so, practitioners create models borrowed from generic techniques in machine learning [1]. This preference for a domain agnostic “data science” could be construed as a lack of concern for existing educational measurement theory in the newer fields of EDM and LA. Conversely, educational measurement might be failing to engage with newer research in computing-based practices.

The first edition of the workshop was held at ITS 2018 [3]. In addition to a round-table and two demonstrations of existing Learning Analytics and EDM applications currently deployed, the half-day ses-

sion included the presentation of three 8–10 pages research papers. The program is available at this link : <http://griemetic.ca/fr/evenements/learning-analytics-building-bridges-between-the-education-and-the-computing-communities/>.

2. TOPICS OF INTEREST

The call for papers mentioned the following list of topics that were of interest, though not exclusively:

- Mutual perception of EDM/LA and educational measurement communities
- Expectations of the educational community towards EDM
- Role of psychometrics in EDM and vice-versa
- EDM tools and methods in education
- Statistical learning methods in psychometrics

3. SCHEDULE

The workshop was half-day and included four papers that were peer reviewed by two experts and the Program committee members. Two demonstrations of practical applications of EDM were presented by our invited speaker Sameer Bhatnagar from Dawson College, Polytechnique Montreal, and the Saltise Association (<https://www.saltise.ca/>).

The four research papers presented were selected from a total of six submissions. They are:

1. Björn Rudzewitz, Ramon Ziai, Florian Nuxoll, Kordula De Kuthy and Detmar Meurers. *Enhancing a Web-based Language Tutoring System with Learning Analytics*.
2. James Shing Chun Yip and Raymond Chi-Wing Wong. *Analyzing Student Performance with Personalized Study Path and Learning Trouble Ratio*.

ABSTRACT

In this tutorial, participants explore design and development considerations for open, pedagogically-based predictive models using the Moodle Analytics API. The tutorial covers aligning models and systems with pedagogical and curriculum needs of the educational program, including interactive exercises in identifying curricular needs to inform educational data mining. We then introduce the Moodle Analytics API, including interfaces for developing Targets, Indicators, Analysers, and Time-Splitting Methods, and including hands-on exercises in which participants use the Moodle Analytics API. The tutorial concludes with a complete basic model developed in PHP using the API.

A laptop capable of installing and running a local copy of Moodle is required for full participation in this tutorial.

Keywords

Educational Data Mining, Moodle, curriculum, pedagogy, open systems

1. INTRODUCTION

In this tutorial, we first explore the educational assumptions that underlie all learning analytics models. These assumptions are often implicit and sometimes even in conflict with one another. Having identified specific goals for a program, we document the requirements for a predictive model to support those goals. As we proceed through the tutorial, we work from the requirements defined in the first exercises to implement models in PHP using the Moodle Analytics API.

This tutorial is followed up with online modules allowing participants to explore each topic in more depth, including peer-reviewed tasks with badges.

2. LITERATURE REVIEW

Over the past few decades, educational data mining systems and models have brought statistical analysis, data mining, and machine learning tools to bear on the teaching and learning process [1,2]. However, even as such predictive models become

more widespread, often they remain focused on “at risk” models that make assumptions about the definition of “student success,” such as completion of a course with a “passing” grade [3,4]. Yet there are many definitions of “student success,” and some programs are not evaluated in terms of the proportion of “passing” students, but in terms of other programmatic outcomes such as accurate identification of those with scholarly potential, influence on pro-social behaviors, or support of student-selected goals and lifelong learning skills [5]. These definitions can inform contemporary educational data mining efforts to identify new relationships and features.

The Moodle Analytics API supports a broad range of such programmatic outcomes, and provides integrated detection, modeling, and notification tools within Moodle [6]. Moodle is an open source learning management system (LMS) used by over 100 million users on over 100 thousand sites in 227 countries [7], providing a robust events and logging system, and as such is ideal as a modern platform for educational data mining, including creating, verifying and implementing predictive models.

3. AGENDA

This tutorial is designed to be delivered in a full day, and contains the following sections:

3.1 Introduction to Moodle Analytics

In this introduction, basic concepts of data analysis in the Moodle environment are briefly covered, and the features of the Moodle Analytics API are introduced.

3.2 Defining and Measuring “Quality Education”

We cannot measure what we have not defined, much less make predictions and advisements to support the quality of the learning process [8]. In this portion of the tutorial, we explore four paradigms [5] of “quality education” in terms of curriculum theory, pedagogy, stakeholders, outcomes, and potential predictors. The tradeoff between accuracy and interpretability of predictions is also discussed.

3.3 Exercise: Defining Quality Education

In this hands-on exercise, participants answer a series of questions about the nature and purpose of education and plot their responses on shared charts. The purpose of the exercise is not to determine a single definition of “quality education,” but to allow participants to unpack assumptions and make explicit the definitions they wish to support in educational data mining.

Elizabeth Dalton and David Monllaó Olivé "Designing and Developing Open, Pedagogically-Based Predictive Models using the Moodle Analytics API" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 770 - 772

3.4 Predictive Model Design Overview

Participants walk through the steps to design a predictive model, including basic data analysis and stakeholder involvement. Benefits and risks of real-time notification systems are discussed.

3.5 Introduction to the Moodle Analytics API

This overview explores the API, including functional components, specific classes to be extended, and required elements in each class.

3.6 Exercise: Prepare Git Repository

Moodle Analytics models are developed as Moodle “plugins.” Participants have an opportunity to set up a Moodle development environment and clone a skeleton Git repository for work on a model plugin.

3.7 Model Review: The Community of Inquiry Model

We review the base model shipped with Moodle Core, the “Students at risk of dropping out” model [9] based on the Community of Inquiry theoretical framework [10]. We discuss design decisions made in implementing this model and review challenges in implementing and evaluating the model for widespread use.

This presentation concludes with an opportunity to connect to a live system with sample data to observe the model in operation. Processes for evaluating learning analytics models are discussed.

3.8 Exercise: Design an Open, Ethical, Pedagogically-Based Predictive Model

Participants design a predictive analytics model “on paper,” defining the learning question or challenge to be resolved, stakeholders, user stories, the target that will be implemented, possible indicators, and a channel for discussion. Working teams present their results to the tutorial participants.

3.9 Development of Targets

The Moodle Analytics API currently supports supervised learning, requiring a training set of data with defined Targets. The Target class is examined in more detail, including the specification of outcome classes, the analyser class, constraints for valid analysables and samples, and the target calculation itself.

3.10 Insights, Notifications and Actions

Insights, Notifications and Actions are coded as part of the Target class. Insights define the text to be used in each outcome class for the model. An array of links to Actions is constructed for use by the recipient of the Notification.

3.11 Exercise: Develop a Target

Participants build on the repository created in the previous exercise to define a simple binary target.

3.12 Development of Indicators

Indicators consist of reusable classes that calculate predictors for use in models. A set of indicators are provided with Moodle Core. Indicators can be used in any model using an appropriate

Analyser (see below). Most of the current indicators calculate values by aggregating log actions and other data over a time splitting interval.

3.13 Exercise: Develop an Indicator

Participants build on the repository created in the previous exercise to define a simple indicator.

3.14 Discussion: Novel Indicators

Indicators are one of the most fertile areas for advanced educational data mining, as they can be extended to take advantage of innovations in feature discovery. Participants discuss potential novel indicators in groups and then present to the rest of the participants.

3.15 Development of Time-Splitting Methods

The time-splitting method classes determine how often to make predictions and how much data (based on time intervals) to include in each prediction.

3.16 Development of Analysers

Analyser classes define the context of the predictions, i.e. one prediction should be generated for every student in each course, or every course in each category, or every learning plan for each student. Analyser classes are usually the most complex components in the Moodle Analytics API.

3.17 Backend Engine and Algorithm Interfaces

The Moodle Analytics API currently supports two backend machine learning engines, one using php-ml and one using Python based on Tensorflow [11]. The php-ml backend provides a regression algorithm, and the python backend provides a feed-forward neural network with one single hidden layer. It is possible to extend these interfaces to make use of other backends and algorithms. Like Indicators, this is another fertile area for Educational Data Mining.

3.18 Exercise: Implement a Basic Model

In this exercise, participants work individually or in groups to extend the provided skeleton to create a simple predictive model using the API. We provide a system with realistic data on which to install and test models, and review model evaluation. The process to submit a completed model to the Moodle Plugins Database is also reviewed.

4. ONLINE MODULES

Participants may continue to explore more advanced API concepts using a series of free online modules.

ABSTRACT

This tutorial will explore LearnSphere, an NSF-funded, community-based repository that facilitates sharing of educational data and analytic methods. The tutorial organizers will discuss the unique research benefits that LearnSphere affords. We will focus on Tigris, a workflow tool within LearnSphere that helps researchers share analytic methods and computational models. Attendees will integrate their analytic methods or models into LearnSphere's Tigris in advance of the tutorial, and these methods will be made accessible to all tutorial attendees. We will learn about these different analytic methods during the tutorial and spend hands-on time applying them to a variety of educational datasets available in LearnSphere's DataShop. Finally, we will discuss the bottlenecks that remain, and brainstorm potential solutions, in openly sharing analytic methods through a central infrastructure like LearnSphere. Our goal is to create the building blocks to allow groups of researchers to integrate their data with other researchers to advance the learning sciences as harnessing and sharing big data has done for other fields.

Keywords

Learning metrics; data storage and sharing; data-informed learning theories; modeling; data-informed efforts; scalability.

1. INTRODUCTION

The use of data to improve student learning has become more effective as student learning activities and student progress through educational technologies are increasingly being tracked and stored. There is a large variety in the kinds, density, and volume of such data and to the analytic and adaptive learning methods that take advantage of it. Data can range from simple (e.g., clicks on menu items or structured symbolic expressions) to complex and harder-to-interpret (e.g., free-form essays, discussion board dialogues, or affect sensor information). Another dimension of variation is the

time scale in which observations of student behavior occur: click actions are observed within seconds in fluency-oriented math games or in vocabulary practice, problem-solving steps are observed every 20 seconds or so in modeling tool interfaces (e.g., spreadsheets, graphers, computer algebra) in intelligent tutoring systems for math and science, answers to comprehension-monitoring questions are given and learning resource choices are made every 15 minutes or so in massive open online courses (MOOCs), lesson completion is observed across days in learning management systems, chapter/unit test results are collected after weeks, end-of-course completion and exam scores are collected after many months, degree completion occurs across years, and long-term human goals like landing a job and achieving a good income occur across lifetimes. Different paradigms of data-driven education research differ both in the types of data they tend to use and in the time scale in which that data is collected. In fact, relative isolation within disciplinary silos is fostered and fed by differences in the types and time scale of data used (cf., Koedinger et al., 2012).

Thus, there is a broad need for an overarching data infrastructure to not only support sharing and use within the student data (e.g., clickstream, MOOC, discourse, affect) but to also support investigations that bridge across them. This will enable the research community to understand how and when long-term learning outcomes emerge as a causal consequence of real-time student interactions within the complex set of instructional options available (cf., Koedinger et al., 2010). Such an infrastructure will support novel, transformative, and multidisciplinary approaches to the use of data to create actionable knowledge to improve learning environments for STEM and other areas in the medium term and will revolutionize learning in the longer term.

LearnSphere transforms scientific discovery and innovation in education through a scalable data infrastructure designed to enable educators, learning scientists, and researchers to easily collaborate over shared data using the latest tools and technologies. LearnSphere.org provides a hub that integrates across existing data silos implemented at different universities, including educational technology "click stream" data in CMU's DataShop (Stamper et al., 2011), massive online course data in Stanford's DataStage and

Kenneth Koedinger, John Stamper, Paulo Carvalho, Philip Pavlik and Luke Eglington "Sharing and Reusing Data and Analytic Methods with LearnSphere" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 773 - 774

analytics in MIT's MOOCdb (Veeramachaneni et al., 2014), and educational language and discourse data in CMU's new DiscourseDB (Jo et al., 2016). LearnSphere integrates these DIBBs in two key ways: 1) with a web-based portal that points to these and other learning analytic resources and 2) with a web-based workflow authoring and sharing tool called Tigris. A major goal is to make it easier for researchers, course developers, and instructors to engage in learning analytics and educational data mining without programming skills.

The main goal of this tutorial is to provide attendees with hands-on experience using Tigris for learning analytics. We hope that this year we will be able to attract attendees that have been exposed to LearnSphere from these past events, although we will have some tutorial activities included for new attendees as well. This tutorial builds off a successful LAK 2018 Tutorial, and tutorial at AIED/EDM 2017.

Activities will include presentations from tutorial organizers. Hands-on sessions will include demos and group work towards implementing analytics. Broadly, this tutorial offers those in the Learning Analytics community exposure to LearnSphere as a community-based infrastructure for educational data and analysis tools. In opening lectures, the organizers will discuss the way LearnSphere connects data silos across universities and its unique capabilities for sharing data, models, analysis workflows, and visualizations while maintaining confidentiality.

More specifically, we propose to focus on attracting, integrating, and discussing researcher contributions to Tigris, the web-based workflow authoring and sharing tool. tutorial submissions in the form of abstracts will involve a brief description of an analysis pipeline relevant to modeling educational data as well as accompanying code. Prior to the tutorial itself, the organizers will coordinate with attendees to integrate their code into Tigris. A significant portion of the tutorial will be dedicated to a hands-on exploration of custom workflows and workflow modules within Tigris. Attendees will present their analysis pipelines, and everyone attending the tutorial will be able to access those analysis pipelines within Tigris to a variety of freely available educational datasets

available from LearnSphere. The goal is to generate -- for each workflow component contribution in the tutorial -- a publishable tutorial paper that describes the outcomes of openly sharing the analysis with the research community.

Finally, tutorial attendees will discuss bottlenecks that remain toward our goal of a unified repository. We will also brainstorm possible solutions. Our goal is to create the building blocks to allow groups of researchers to integrate their data with other researchers we can advance the learning sciences as harnessing and sharing big data has done for other fields.

2. ACKNOWLEDGMENTS

This workshop is supported by National Science Foundation grant ACI-1443068 toward the creation of LearnSphere.org

ABSTRACT

There is growing evidence that digital games are an effective medium for learning. Games also present distinctive challenges and opportunities for educational data mining (EDM). Many games feature complex, open-ended tasks and unexpected learner behaviors. In addition, games provide vast amounts of fine-grained data about learners' behaviors, offering a new window into student learning processes. Game-based learning raises questions that require new computational techniques and methodologies to enhance our understanding of the moment-to-moment signatures of engaged learning. To explore these questions, we have convened a workshop on EDM & Games: Leveling Up Engaged Learning with Data-Rich Analytics. The purpose of the workshop is to build a community with shared interest in this emerging area, foster future collaborations, and identify new opportunities for EDM that are enabled by data from student interactions with game-based learning environments. The half-day workshop features a program of oral paper presentations, group discussions, and an invited speaker, each exploring questions about how EDM and games can be leveraged together to enhance our understanding of engaged learning in a range of educational contexts.

Keywords

Game-based learning, serious games, game-based assessment, multimodal analytics, engagement.

1. INTRODUCTION

Recent advances in educational data mining (EDM) are creating new opportunities for game-based learning. Games have long been recognized for their capacity to engage players in immersive virtual worlds and complex problem scenarios. Now, there is growing evidence that games are also an effective medium for enhancing learning [1, 2]. Games for learning have

been developed across a broad range of educational domains, including science education [3, 4], mathematics education [5], language learning [6], civic education [7], and patient education [8].

As learners interact with educational games, rich streams of in-game behavior data are generated that can be modeled and analyzed using EDM techniques. These data streams contain timestamped records of key game events, such as interactions with non-player characters, movements between locations, and manipulations of virtual objects. Increasingly, they also include multimodal sensor data, such as eye tracking, facial expression, posture, and biometric data [9, 10]. The increasing availability of trace-level data from games has created new opportunities for investigating methods to analyze and model learner behavior in these environments. The resulting models hold promise for enriching our understanding of learning, problem solving, and engagement [11, 12], as well as enabling data-driven pedagogical functionalities to create personalized game-based learning experiences [13].

In light of these advances, a variety of questions have begun to emerge at the intersection of EDM and games:

- Which EDM techniques are best suited for addressing the distinctive challenges posed by game-based learning, such as open-ended tasks, unexpected learner behaviors, and balancing learning and engagement effectively?
- How can we leverage EDM techniques to inform evidence-based design principles for game-based learning?
- What are the unique contributions that EDM can provide toward enhancing our understanding of the moment-to-moment signatures of engaged learning.

2. WORKSHOP GOALS

To explore these questions, the workshop brings together researchers interested in the intersection of EDM and games to better understand student learning and engagement using data-rich analytics. It showcases recent research on EDM in games for learning, training, and education. A key focus is leveraging novel data mining techniques and methodologies to enhance our understanding of student learning and engagement, as well as to enable enriched learning experiences that are both effective and engaging.

Jonathan Rowe, Bradford Mott, Luc Paquette and Seung Lee "EDM & Games: Leveling Up Engaged Learning with Data-Rich Analytics" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 775 - 776

The workshop covers a broad range of topics at the intersection of EDM and games across different educational settings (e.g., schools, training, online learning), student populations (e.g., primary, secondary, post-secondary), and educational domains (e.g., science, mathematics, military training). It has been designed to build a community of researchers that share common interests and to create opportunities for future collaborations. It has also seen the assembly of a multidisciplinary program committee consisting of more than 20 scholars spanning academia and industry, several of whom have also contributed to the workshop as authors.

3. WORKSHOP PROGRAM

The half-day workshop is structured around a series of oral paper presentations, group discussions, and an invited talk. Accepted papers cover a range of topics at the intersection of EDM and games, including the following:

- An investigation of problem-solving strategies of both expert humans and AI agents playing Atari 2600 games, including visualizations of game data to compare agent policies and human expert strategies.
- An examination of off-the-shelf data-mining techniques to predict student quitting and assessment performance with two online middle school science learning games.
- An investigation of how much data is needed in gameplay sessions to predict student performance, and thus inform how teachers should allocate help and attention toward students. Teachers may not always be able to attend to information dashboards in the classroom, so understanding how to alert teachers of student needs is critical.
- An approach to detecting student affect using multimodal sensors in game-based learning environments. The authors examine two sensor modalities, posture and electrodermal activity, to predict the affective states of students and evaluate different types of multimodal data fusion techniques to obtain the best classification accuracy.
- A data-driven approach to predicting students' challenge outcomes using a game-based learning environment for genetics. The model predicts two categories of challenge outcome: quit or complete. The paper explores and compares an extensive set of machine learning models for predicting student performance.

4. CONCLUSION

Game-based learning environments have significant potential as a medium for engaging learners in complex problem-solving scenarios. The rich data streams produced by student interactions with games are creating new opportunities for applying EDM to enrich our understanding of learning, problem solving, and engagement. This workshop represents an important step toward realizing this vision by cultivating a scholarly community that seeks to understand how we might foster engaged learning through the integration of EDM and game-based learning technologies and methods.

ABSTRACT

This tutorial explores causal discovery algorithms in Tetrad¹ implemented in LearnSphere's Tigris workflow tool². The Tetrad software suite contains algorithms that search for causal models from observational and experimental datasets [10], and has been productively applied to many educational datasets [8, 6, 3]. LearnSphere's Tigris is a free online workflow authoring tool and data mining infrastructure for custom analyses of new and existing data formats, including the educational data repository DataShop [11]. The tutorial teaches the fundamentals of causal discovery with hands on work in Tetrad, and teaches integrated causal data-mining with hands on work in Tigris. Attendees will gain experience sharing their results and methods in Tigris with others as well as connecting their analyses to thousands of datasets available in DataShop.

1. INTRODUCTION

As more educational technologies are created, more data is being logged and available to researchers. Mining this data for information concerning what pattern of student behaviors cause better learning outcomes is crucial if we are to intervene, either in the design of the online material, or in the student's behavior more directly. The gold standard for determining causal relationships is randomized controlled experiments, but these cost money and time, and are often unable to answer questions about the mechanisms by which an intervention causes learning. Tetrad contains algorithms that can mine both experimental and observational datasets for information about the causal relationships that might have produced the observed data. It has been used to guide follow-up experiments in educational research [5]. With an abundance of datasets available and causal questions at the center of all kinds of science, educational data-mining for causation is an increasingly important task.

Richard Scheines, Peter Schaldenbrand and Kenneth Koedinger "Causal Discovery with Tetrad in LearnSphere's Tigris" In: *Proceedings of The 12th International Conference on Educational Data Mining (EDM 2019)*, Collin F. Lynch, Agathe Merceron, Michel Desmarais, & Roger Nkambou (eds.) 2019, pp. 777 - 779

Tetrad is a standalone Java program developed by the Philosophy department at Carnegie Mellon University and more recently in conjunction with the Department of Biomedical Informatics at the University of Pittsburgh. The aim of the program is to provide sophisticated methods of creating, searching for, estimating, and testing causal and statistical models of both experimental and observational data. No prior programming experience is needed to use Tetrad.

Much of the functionality of Tetrad has been included in an online workflow tool called Tigris. The LearnSphere project created Tigris to connect multiple data sources to analytical tools that are open source and available for collaboration. LearnSphere.org provides a hub that integrates existing data silos implemented at different universities, including educational technology "click stream" data in CMU's DataShop[11], massive online course data in Stanford's DataStage and analytics in MIT's MOOCdb [12], and educational language and discourse data in CMU's DiscourseDB [1]. Researchers can share their data mining code in the Tigris tool by adding it to the open source repository³ such as the Performance Factors Analysis[4] program or the Feature Extractor [13].

The advantages of the Tetrad implementation in Tigris are numerous. Since Tigris is a web based tool, workflows can be shared amongst anyone with a computer. There is no need to worry about having Java on your computer or downloading different versions of Tetrad. The owner of a workflow can share their Tetrad analyses on Tigris with whomever they wish. In addition to shareability, Tetrad on Tigris is connected to the educational data repository DataShop. This connection allows for easy access and permission control of data in a Tetrad analysis.

Tigris workflows are executed and saved remotely on secure servers. LearnSphere has a scalable infrastructure that allows for computation on large datasets, and so the limitations on computation are not influenced by the user's machine. The analyses are run remotely, so the code still runs regardless of the status of the user's machine. The analyses can be accessed from any computer and are safely saved.

In this tutorial, we will explore the causes of learning in online courses using Tetrad in Tigris. The organizers will explain how to interpret the output generated by algorithms in Tetrad and how to build a Tigris workflow that utilizes data in DataShop to determine the causes of learning with

³<https://github.com/LearnSphere/WorkflowComponents>

Tetrad. The attendees will gain access to a dataset that was collected from an online college course. The data contains variables such as pages viewed, activities performed, quiz scores, and final exam grades. Using this data, the attendees will generate causal models in a similar fashion to [2] and [3].

2. THE TUTORIAL

2.1 Schedule

Table 1: Tutorial Schedule: July 2nd, 2019

Time	Item
1:00pm	Introduction and Definition of Causal Discovery and Tetrad
2:15pm	Demonstration: Building a Tigris workflow that utilizes DataShop data and Tetrad
2:45pm	Break
3:00pm	Hands-on: Determine the causes of learning using DataShop data in Tigris.
4:00pm	Closing / High Level Discussion

2.2 Introduction and Definition of Causal Discovery and Tetrad

Richard Scheines is the Dean of the Mariana Brown Dietrich College of Humanities and Social Sciences at Carnegie Mellon University and a Professor in the Department of Philosophy. His research is on causal discovery, and in particular, the problem of learning about causation from statistical evidence. The theoretical and computational dimensions of Dr. Scheines's work are implemented in the Tetrad causal discovery tool. In this first segment of the tutorial, Dr. Scheines will introduce the theory behind statistical causality and teach attendees about graph theory. This will give attendees the background necessary to understand the underlying workings of the causal discovery algorithms in Tetrad.

2.3 Demonstration: Building a Tigris workflow that utilizes DataShop data and Tetrad

Peter Schaldenbrand is a developer on the LearnSphere project and researcher in the Human-Computer Interaction Institute at Carnegie Mellon University. He has authored many analysis components in the Tigris workflow tool and has integrated Tetrad's causal search algorithms into Tigris. Mr. Schaldenbrand will introduce attendees to the online educational data mining tool, Tigris, in a demonstrative way in this segment of the tutorial. Attendees will learn how to view another researcher's workflows and even build off of them while using their own data. The connection between DataShop data and the analytical tools in Tigris will be demonstrated. Mr. Schaldenbrand will introduce many of the educational data mining tools implemented in Tigris including the Tetrad suite. Lastly, Mr. Schaldenbrand will build a workflow which will setup the attendees to build their own workflows in the hands on section.

2.4 Hands-on: Determine the causes of learning using DataShop data in Tigris.

Tutorial attendees will gain access to two datasets in DataShop. Both datasets were generated from Massive Open Online Courses, but the courses were for different subjects

and took place at different universities. Each dataset contains variables that measure pre- and post-test assessment as well as resource usage such as videos watched, activities completed, and pages read.

Attendees will import the data directly from DataShop into a new Tigris workflow which they have created. They will learn to clean the data for usage with the Tetrad components. They will then use the Tetrad components to explore the causes of learning within these MOOC environments. This analysis will be similar to that performed in [2] and [3].

3. OBJECTIVES AND OUTCOMES

One of the objectives of this tutorial is to introduce the importance of causal analysis to the educational data mining community. Many papers focus on finding interesting correlations in data such as [7] and [9]. These correlations can be fascinating but only give small clues into how to make actionable interventions in curricula, intelligent tutoring systems, or classrooms to increase learning. This tutorial will demonstrate that important causal relationships can be mined from observational data and that these relationships can give insight into real interventions on student learning.

This tutorial will also display the importance of making analyses sharable and introduce easily reproducible workflow capabilities in Tigris. Software versioning, data permissions, and hidden calculations plague the reproducibility of research results. In Tigris, versioning is hidden from the user allowing anyone with a computer to use the tools. Data permissions are handled through the safe infrastructure of DataShop, and all calculations and parameters are visible in the Tigris workflow pipeline. This tutorial will demonstrate that doing research in Tigris is a great way to support reproducibility and shareability.

One outcome of this tutorial is that attendees will be familiar with using data from DataShop in a Tigris workflow. They will request access to a dataset which they will import into a Tigris workflow under the guidance of the organizers. They will then gain familiarity with the Tetrad algorithms and analyze the results with the organizers.

Once the attendees are familiar with creating causal models in a workflow, they can move onto working on their own research questions. Tutorial attendees will discuss what causal relationships they would like to investigate and try to expand on the use cases of Tetrad. They may present a workflow that utilizes Tetrad and their own datasets to the other attendees. This tutorial will promote the importance of causal reasoning in education with the intention of making productive interventions on student learning.
